Cold causes contraction of the blood-vessels of the skin; increased heart action and increased blood-pressure; increased activity of the skeletal muscles, either shivering or voluntary and more or less purposeful, accompanied by increased combustion of carbohydrates; increased respiration; it has a tendency to produce sluggishness of the alimentary tract—i.e. of bowel movement; it increases the flow of urine; and if long-continued (a cold climate) it tends to diminish the pigmentation of the skin. Now if we turn to Cushny and read his account of the action of adrenaline, we find that it produces identically the same effects. It is true that he does not mention any effect on pigmentation—this could hardly develop during a brief, pharmacological experiment—but since in Addison's disease a greater or less reduction in the formation of adrenaline leads to a greater or less degree of pigmentation, it is a fair inference that adrenaline acts to prevent or reduce pigmentation of the skin. Otherwise, the effects of cold and of adrenaline are exactly parallel; and to read Cushny's account of the action of adrenaline with this point of view in mind is to realize that here we have no ordinary drug producing a multitude of accidental and purposeless effects on the various tissues and organs of the body, but an agent which the organism has developed for the purpose of accomplishing a specific object—viz., to enable it to adapt itself to cold. It constricts some blood-vessels, dilates others; stimulates some organs, depresses others; corresponds in its general action to the effect of stimulation of the sympathetic nerve fibers, and yet takes care not to stimulate the sweat glands (which, indeed, would defeat its purpose), but on the other hand goes out of its way to stimulate the hydrolysis of glycogen in the liver, thus filling the blood with sugar; and while it constricts so many blood-vessels, it takes care to leave those supplying the skeletal muscles well dilated. In addition it causes dilatation of the pupil with retraction of the eye-lids and protrusion of the eyeball which, while it did not occur to me to mention it, is a characteristic effect of cold. This absolutely identical action of cold and of adrenaline can hardly be an accidental coincidence; it must mean that cold acts to stimulate the secretion of adrenaline. And what a clear light this action of adrenaline throws upon the wonderfully delicate and complicated mechanism of the human body! It is so constituted that a comparatively simple substance like adrenaline can produce all these diverse and complicated reactions, which yet all work together to a common purpose. It might be compared to a musician pulling out certain stops on an organ and pushing in others to get a desired effect.

And the identity of the effects of heat and of diminished adrenaline secretion is no less absolute. When an individual of the white race removes to a hot climate he suffers from general languor and debility; he constantly feels tired and is unable to concentrate his attention and carry on his ordinary occupation with the accustomed vigor; his muscles lose their tone and his heart action is not so strong and regular and his blood-pressure is lower than normal; he is apt to have feelings of dizziness and faintness, and headache; he loses his appetite, his stomach is easily upset, and attacks of diarrhea may come on frequently and without obvious cause; and his skin gradually becomes pigmented. In fact, some of these symptoms to a greater or less degree —especially the "tired feeling"—are a common experience with most of us as the cold of winter changes more or less suddenly to the warm weather of spring and the heat of summer. Now, when we compare these effects of heat with the effects of diminished adrenaline secretion as it occurs in Addison's disease, we find them absolutely identical, except that in Addison's disease the symptoms are more marked and progressive as the destruction of the adrenaline-forming tissues becomes more complete. This is noticeably the case with the pigmentation of the skin, which in Addison's disease may vary in grade from a light yellow to a deep brown or black. In other words, the absence of pigmentation of the skin in the white race is due, directly or indirectly, to a high degree of adrenal activity; and the vigor and enterprise of the white race is due to the same cause—both, of course, being the result of ages of adaptation to environment and being associated with a multitude of other characteristics physical and mental more or less dependent upon them. Conversely, the black race owes its pig-

mented skin and its sluggishness to a low degree of adrenal activity; and the yellow race its yellow skin and only moderate enterprise to an intermediate degree of adrenal activity; the brown races being intermediate between the yellow and black, and the brunettes of the white race showing less adrenal activity than the blonds. It might seem strange that a single agent—adrenaline—should control so many characteristics, ranging from pigmentation of the skin to muscular activity and enterprise; but since the conditions of environment to which these characters are adapted are associated in nature it is a natural result that these characters should be associated in the organism, although remarkable that they should depend upon a single controlling agent. The color of the hair seems to be less easily influenced by environment than that of the skin; thus even the yellow races and the brunette members of the white race retain the black hair of their original tropical ancestors; the development of adrenal activity, however much it may have diminished the pigmentation of the skin, having had no effect in changing the color of their hair, although other causes seem to have modified its character. It is only in the blond members of the white race that the color of the hair is greatly modified, and this may be because it was only among the snows of the northern regions that black hair became conspicuous enough to make it an important factor in the survival of the individual.

This hypothesis might throw some light on arteriosclerosis. Sir William Osler used to say that some individuals have poorer rubber in their arteries than others, and we might expect that brunettes and members of the darker races would have less powerful elastic coats in the walls of their arteries than blonds, as a result of having developed in warmer climates where lower blood pressure and less muscular activity would prevail. Thus, if an individual of a brunette or black race indigenous in a warm or hot climate, and consequently inheriting arteries adapted to only a relatively low blood-pressure, should remove to a cold climate where the adrenal glands would be stimulated to increased activity, it might be expected that the elastic coats of the arteries could not withstand the higher blood-pressure resulting and would give way and degenerate, leading to arteriosclerosis. I do not know of any statistics of arteriosclerosis showing its relative frequency in blonds and brunettes, but they might be worth collecting. (In fact, it might prove of value to record the degree of coloration of the patient in all medical histories.) It is stated in Osler's "Practice of Medicine" that *aneurysm* is more common among the negroes than among the white population in the southern part of the United States; whereas in India it is rare among the natives, probably on account of their low blood-pressure. And apoplexy and paralysis are more common among negroes than among whites. It would seem that members of dark races are safe enough so long as they remain in their natural hot climate, but when they remove to a colder climate the increased adrenaline formation raises their blood-pressure to a degree higher than their arteries are built to withstand and the elastic coats give way, resulting in arteriosclerosis with aneurysm and apoplexy if exciting causes supervene. And the same thing might be true in less degree of brunettes. In animals arteriosclerosis can be produced experimentally by the intravenous injection of adrenaline. Possibly the wearing of very light clothing in cold weather may stimulate the formation of adrenaline to an excessive degree and favor the development of arteriosclerosis.

On the other hand, when an individual accustomed to a cold climate removes to a hot one, the condition of debility resulting from depressed adernal activity may predispose to acute infectious diseases, tuberculosis, etc. And since the high bodily temperature of fever has the same effect on the organism as external heat, it probably depresses the activity of the adrenal glands, and thus produces the debility and prostration and low blood-pressure, and also the pigmentation of the skin which occurs in protracted fevers. Cold bathing in fevers seems to have a beneficial effect even when it does not lower the temperature appreciably, and may probably act by stimulating the formation of adrenaline, thus raising the blood-pressure and promoting the flow of urine with elimination of toxins, and raising the tone of the system generally, especially the nervous system. (But if the heart is greatly weakened in fevers, this cold bathing may by increasing the blood-pressure cause cardiac failure.) The wet-pack, so highly recommended by Osler in neurasthenia, may act in a similar manner; the lack of tone, especially in the blood vessels, and the general debility in nervous prostration, etc., being perhaps due, in part at least, to hyposecretion of adrenaline. We find extreme examples of the depressing effects of heat in cases of heat exhaustion and sunstroke or thermic fever, which are especially liable to attack members of the white race living in a hot climate. And the symptoms of these disorders point almost conclusively to their being the result of depressed adrenaline formation. Thus, in heat exhaustion, the physical depression, giddiness, faintness, pallor, small pulse, weak heart action, unconsciousness, coma and death suggest an acute attack of Addison's disease; *minus*, of course, the pigmentation, which does not have time to develop. There may also be gastrointestinal disturbances, which in all these cases of deficiency of adrenaline are no doubt due to congestion of the abdominal viscera resulting from vasodilatation of the splanchnic vessels; just as the sluggishness of the bowels in a cold climate results from constriction of these vessels by adrenaline, with ischemia of the abdominal viscera, in addition to the contraction of the pyloric, ileo-colic, and internal anal sphincters produced directly by the adrenaline (Cushny). Sunstroke appears to be a still more striking example of acute failure of adrenaline secretion due to depression by excessive and prolonged high external temperature; it is the *heat* and not necessarily the direct rays of the sun that cause it, as shown by the frequency of its occurrence at night, especially in overcrowded barracks and on shipboard. Anxiety, fatigue, deficiencies in the diet, and bad hygienic surrounding also predispose to sunstroke. The victim may be struck down within an hour with symptoms of heart-failure, dyspnea and coma. (It is to be noted that adrenaline is destroyed in the tissues as rapidly as it is secreted into the blood, and thus there is no reserve

supply and sudden and severe depression of the secretion by heat may deprive the organism of it completely.) More usually there is headache, dizziness, a feeling of oppression, sometimes nausea and vomiting and diarrhea; then insensibility and coma, with complete relaxation of the muscles, or there may be convulsions followed by marked mental disturbance. These symptoms, although more acute, exactly parallel those of Addison's disease (except the pigmentation) where also we may have convulsions and a noisy delirium preceding death, with urgent dyspnea. Even when recovery from sunstroke appears to be complete, there may remain a permanent inability to bear high temperatures due probably to the adrenal glands, etc., being permanently impaired by the great depressing effect of the high temperature and hence more susceptible to repeated depression by heat. Also, loss of the power of mental concentration and failure of memory are frequent sequelae, and there may be marked mental disturbance. The most successful treatment of sunstroke—applying cold to the body by an ice bath, etc., or employing enemata of ice-water—is just what we should expect would be, according to this hypothesis, the best means of stimulating adrenal action. It might be worth while to try the injection of adrenaline intravenously in severe cases of sunstroke, especially after venesection, when it might be administered well diluted in salt solution. Alcohol predisposes to heat exhaustion and sunstroke, and may act by interfering directly or indirectly with the action of adrenaline, as is suggested by its dilating the vessels of the skin and lowering the blood-pressure and general tone of the system. It is interesting to note that in the United States negroes are often attacked by sunstroke, though seldom in their natural tropical climate. This may be because their adrenaline-forming tissues are imperfectly adapted to a cool climate and working, perhaps, beyond their capacity, are more susceptible to sudden failure when subjected to the depressing influence of an unusually high temperature. In cases of ordinary *sunburn* of moderate severity, involving only the face, neck, arms and legs, apart from the discomfort caused by the tenderness of the skin, there is an element of more or less marked prostration entirely out of proportion to the degree of actual injury to the skin. Probably this is caused by depression of adrenal activity by the heat, as is also the feeling of giddiness and faintness and perhaps slight nausea; also the pigmentation of the skin which remains after healing is no doubt a result of diminished adrenaline formation. It would seem that mere diminution of adrenaline secretion does not of itself necessarily cause pigmentation of the skin, although a necessary factor in pigmentation. As a rule, it seems necessary also that the sun should act directly on the skin to cause it to become pigmented. It may be that the sun acts merely as an irritant, because in Addison's disease, while pigmentation may finally become diffuse, it may for a long time be limited to exposed parts, and is always deeper there and also wherever the skin is compressed or irritated, as by the waistband. This is true also of other conditions where pigmentation occurs, and its association with trophic neuritis in localized scleroderma and other disorders suggests that there is also a trophic nervous element which may be influenced by irritation. Thus in these conditions of depressed adrenal action we might conclude that pigmentation of the skin results from the action of the sun or other irritants upon the skin in the more or less complete absence of adrenaline.

Furthermore, this hypothesis leads us to a new conception of the nature of *pellagra*. It would suggest that pellagra is a type of Addison's disease resulting from functional disturbance of the adrenal glands and chromaffin tissues due to the depressing effects of heat, occurring in individuals who are not adapted by race to the climate in which they live, and resulting in a hyposecretion of adrenaline. This disturbance is most marked in the spring of the year when the change from cold to warm weather normally exercises a depressing influence on these tissues; but due to the lack of adaptation to the climate, this reduction in the formation of adrenaline is excessive and abnormal. Exacerbations occur also in the fall, when the change from warm to cold weather makes an extra demand upon these tissues, which in their disturbed and weakened condition they are not prepared to meet. And in pellagra this functional disturbance of the adrenaline-forming tissues may tend to become chronic and progressive, so that each exacerbation in the spring and fall is followed by further deterioration and loss of function. Let us compare the features of pellagra with those of Addison's disease as stated by Osler. In both diseases the majority of cases occur between the twentieth and the fortieth years. Pellagra sets in with symptoms of weakness, headache and depression; disturbances of the alimentary tract—sensations of heat in the mouth, congestion of the mucous membrane, anorexia, nausea, vomiting, dyspeptic symptoms, and diarrhea are common. These symptoms are similar to those of Addison's disease, and in both cases the gastrointestinal disturbances are no doubt due to congestion of the splanchnic area resulting from absence of the normal vaso-constricting influence of adrenaline. Then there is the pigmentation of the skin. In Addison's disease, where exposure to heat or directly to the sun is not an exciting cause, the pigmentation is gradual and progressive, although occurring first and being deeper on exposed parts; whereas, in pellagra the effects of the heat and sun produce a condition more closely resembling an ordinary sunburn erythema with puffy swelling, affecting especially the exposed parts. The skin becomes darker and desquamates, after which some pigmentation remains. (This puffy swelling, which occurs also in ordinary sunburn, is out of all proportion to the degree of inflammation and suggests an edema resulting from lowered blood-pressure due to lack of adrenaline.) With repeated attacks of pellagra the skin may become dark in color and erythema may occur on protected parts also, thus more closely resembling Addison's disease. Sometimes in pellagra trophic disturbances of the skin may occur—vesicles and bullae containing serum or pus, which gradually dry with the production of fissures; and with repeated attacks the skin may become indurated and thickened, and later atrophied and thinned. These symptoms appear to have no counterpart in Addison's disease, which

may be due to its more rapid course; but they suggest somewhat the trophic disturbances in diffuse scleroderma and may be due to a toxemia resulting from the hormonic disturbance of other internal secretions (e.g. the thyroid) or may be of nervous origin. The nervous symptoms in pellagra—spastic paralyses, disturbances of sensation, loss of reflexes in the legs—are due to degenerations in the spinal cord; and the paralysis of the sphincters may be due to these also, but adrenaline normally stimulates the sphincters and the lack of it may favor their relaxation; and the mental impairment and dementia in pellagra are associated with atrophy of the brain. All these lesions in the central nervous system may be due to a toxemia resulting from disturbance of the other internal secretions, or they may be largely due to impaired nutrition resulting from circulatory disturbances due to lack of adrenaline. The headache, vertigo, confusion, dullness, lassitude, depression, etc., characteristic of pellagra all have their counterparts in Addison's disease where also mental symptoms, noisy delirium, may develop if the disease is sufficiently prolonged. Probably Addison's disease is not protracted enough for the degenerations in the spinal cord and cerebral atrophy to develop. The acute form of pellagra shows a still more striking resemblance to the acute form of Addison's disease—marked prostration, severe diarrhea, delirium or stupor with death, occurring in a few weeks from the onset. But acute pellagra is distinguished from acute Addison's disease by the presence of fever and more marked delirium, and this is to be expected as a result of the exciting cause in pellagra—exposure to heat—and in this it resembles an attack of sunstroke or thermic fever which is practically identical with an acute attack of pellagra. In the chronic form of pellagra the attacks are milder, but tend to recur each year, and each attack may leave the patient (and the adrenaline-forming tissues) in a worse condition. Death in pellagra occurs from exhaustion or cachexia or some intercurrent disease precisely as it does in Addison's disease. But on the other hand succeeding attacks of pellagra may not be more severe than previous ones—it is simply a case of adrenal activity being abnormally depressed each spring, with no permanent damage to the adrenal glands and chromaffin tissues. (Compare the usual increased susceptibility to repeated attacks of pellagra with the increased susceptibility to the effects of heat following sunstroke—in both cases the adrenaline forming tissues are more or less permanently damaged by the depressing effects of heat and rendered more susceptible to further depression with a repetition of the exposure.) Finally, *arsenic* seems to be of special value in the treatment of both pellagra and Addison's disease. Thus there would seem to be an almost exact parallel between these diseases, and there seems every reason to consider pellagra as a disease resulting from functional adrenal insufficiency.

As regards the theory that pellagra is due to a defect in the diet, the evidence in favor of this view is very suggestive but hardly convincing. Pellagra does not result from a deficient diet, nor does recovery from pellagra follow upon improvement in the diet, with sufficient promptness and uniformity to make it seem probable that the diet alone is at fault. And if pellagra is due to deficiency in the diet, why should it occur in the spring and fall of the year, both in its onset and in its recurrences or exacerbations? And yet the relationship of deficient diet to pellagra seems indisputable. Now this hypothesis of hyposecretion of adrenaline being the fundamental feature of the disease will explain both its occurrence in the spring and also its relation to diet. Diet may be a predisposing cause of pellagra by lowering the vitality and resistance of the entire organism and thus lessening its power of adaptation to changes in environment. And, far more important, it may be a contributing cause second only to the depressing effect of heat in the following way: Adrenaline is rapidly destroyed in the tissues and must be continuously formed and secreted into the blood; it is a *nitrogenous* compound (an amine) and hence can be formed only from nitrogenous food; hence the adrenaline-forming tissues must require a continuous supply of nitrogenous food to produce adrenaline. Now if the diet is deficient in nitrogenous food and at the same time the adrenaline-forming tissues are depressed by heat, and while in this depressed condition have to compete with all the other tissues of the body for their supply of this food when there is not enough to go around, it seems likely that they may fail to get their share and the result would be a further lessening in the amount of adrenaline formed.

According to this view of pellagra it might be expected that the disease would affect principally members of the white race, and especially blonds, living in climates where the heat is great during the spring and summer but the winters comparatively cold; and members of the black race living in a cool climate with spells or seasons of very hot weather, because in these conditions the adrenaline-forming tissues would be overworked during the cold weather of winter and hence especially liable to break down from the depressing influence of heat in the spring. The latter seems to be the case with negroes living in the United States, where they seem more susceptible to the disease than whites. As for members of the white race, pellagra has long been prevalent in parts of southern Europe, particularly in Italy and Roumania; also in Spain, Portugal and France, and in Egypt. In the southern part of the United States it has occurred only since the Civil War and has been prevalent only during recent years; and here its attacks are not confined, as in Europe, almost entirely to laborers of the poorer classes and the disease takes a more serious form. Now I believe these facts can be accounted for on the basis of my hypothesis. It is a matter of history that members of the northern blond races—Lombards, Goths, Vandals and Normans—invaded southern Europe centuries ago and settled there and mingled their blood with that of the brunette races they found there. This introduced an extensive strain of blond blood into these countries of southern Europe, and many of the present inhabitants of these countries are predominantly blond, while all have more or less of a blond strain. Now, through the course of these centuries this blond strain has been adapting itself to a climate which presents an extreme degree of heat in the spring and summer. These blonds

originally possessed very active adrenal tissues inherited from long ages of adaptation to cold northern climes, and probably for many generations the more susceptible blonds (especially if they did not happen to be persons of wealth and leisure who could take their ease and command all the comforts and luxuries that serve to temper the extremes of heat and cold) suffered from heat exhaustion and sunstroke and the many intercurrent affections that attack those whose vitality is lowered in a hot climate by the depressing effect of heat on adrenaline secretion. But as a result of adaptation and natural selection over a period of many generations, and largely as a result of the admixture of brunette blood, the descendants of these blond races gradually developed a tolerance of the climate and instead of acute attacks of heat exhaustion and sunstroke following the heat of spring, they developed sub-acute or chronic attacks of sunstroke—i.e., pellagra; at first perhaps acute pellagra, then the milder chronic form, and finally the form in which subsequent attacks are no more severe than preceding ones, leaving no permanent damage, and amounting to little more than an exaggerated form of "spring fever." Thus in Italy in recent years the mortality has been as low as four per cent., and the disease has been practically confined to peasants who perform hard manual labor with poor food and exposed to the full effects of the climate. Now in the United States the members of the white race who settled our southern states had until the Civil War slaves to do their manual work, and thus largely escaped the full effects of the climate, and for all practical purposes could surround themselves with an artificial cool climate. But since the Civil War they have been more exposed to the effects of the climate and many of them being of the blond type they were liable to heat exhaustion and sunstroke and have only recently reached the stage of pellagra (subacute or chronic sunstroke) and have not yet acquired the immunity to it of the Italians. Hence, as Osler stated, "in the United States the outlook in pellagra is regarded as serious, if not as regards death, certainly as regards ultimate recovery," and he stated further that the disease has spread with extraordinary rapidity in the United States in the last few years. It is a difficult disease to treat. Good food and change to a cooler climate and rest with symptomatic and supporting treatment, arsenic and strychnine, and perhaps cold bathing or sponging and the wet pack seem to be indicated. Adrenal gland therapy has not proved of much value in Addison's disease, and probably would not here. It is interesting to note that in *beriberi*, where a deficiency of nitrogenous food seems to be the principal factor, excessive heat is an important exciting cause and it may be that depression of the adrenalin-forming tissues plays a part here also; some authorities consider that the diet theory alone is not an adequate explanation of the disease. Overcrowding and lack of proper and regular food predispose to beriberi just as they do sunstroke, and the premonitory symptoms of beriberi—languor, depression, tired feeling—suggest deficiency of adrenalin; also it is significant that peripheral neuritis may be a sequel of sunstroke. Beriberi occurs principally in the darker races in their natural climate and pigmentation is not noticeable as a symptom. Their degree of adrenal action is already low and beriberi may represent their peculiar way of reacting to a further depression of this secretion.

Increased pigmentation of the skin occurs in a number of other disorders besides pellagra and Addison's disease, and some of these are associated with or dependent upon disturbance of thyroid secretion as exophthalmic goiter and diffuse scleroderma which may be mistaken for Addison's disease. In exophthalmic goiter, which is supposed to be due to overactivity of the thyroid gland, the disturbed heart action, combined with the vasomotor dilatation, and the vomiting and diarrhea, weakness of the muscles especially of the legs, depression and other mental symptoms—and especially the symptoms in acute cases with intense vomiting and diarrhea, rapid action of the heart, and great throbbing of the arteries—suggest the symptoms of Addison's disease, plus exophthalmos and tremor. It may be that the thyroid secretion, when in excess, neutralizes adrenalin or counteracts its effects on the organism. There may be hormonic relations between adrenalin and the secretions of the thyroid and other ductless glands and disturbance of the function of one of them may disturb more or less the action of the others as well as of the various tissues and organs of the body. Thus the skin lesions in long standing cases of pellagra suggest those in certain cases of scleroderma, as do the spots of leucoderma in Addison's disease. Note also the persistence of the thymus gland in certain cases of Addison's disease. Note also the extreme sensitiveness to cold in scleroderma and in cretinism and myxedema, which conditions are probably all due to disturbance of thyroid secretion. The pigmentation and also the feelings of faintness, nausea, and vomiting ("morning-sickness") of *pregnancy* may be due to deficiency of adrenalin. The pigmentation of the skin in arthritis deformans may be due to disturbance of the internal secretions, as is suggested by the fact that extracts of the thyroid and thymus glands are beneficial in some cases; and the frequent occurrence of arthritis deformans in women about the menopause suggests that this form of it may be due to a toxemia resulting from disturbance of the internal secretions. Pigmentation occurring in advanced cases of *arteriosclerosis* and in *osteitis deformans* may be due to decreased adrenalin-formation resulting from sclerotic changes in the adrenal glands. Pigmentation may result from chronic poisoning by *arsenic*, and it is a curious fact that the symptoms of arsenical poisoning suggest a deficiency of adrenalin—the congestion of the alimentary tract cannot be explained as resulting from the corrosive action of the arsenic. Arsenic may destroy adrenalin directly or it may counteract the effects of adrenalin at its point of action. And yet small doses of arsenic are beneficial in Addison's disease and in pellagra. Then there are certain other disorders in which pigmentation of the skin occurs, such as *hemochromatosis*, *ochronosis*, and certain forms of diabetes; also in melanotic tumors and locally in various trophic nervous disorders. In these cases it is probably due to a disturbance of the hormonic interactions

of the various internal secretions, whose actions and interactions are but little understood and probably very complicated. Glycosuria may be produced in animals by the injection of adrenalin; and it may be that in a member of the white race acclimated to a tropical climate the adrenalin may set free in the blood more sugar than the muscles can use in the limited amount of activity compatible with the hot climate, and this excess of sugar in the blood may lead to glycosuria.

NORTH STREET AND WARD'S LANE.

EMPLOYMENT OF DIATHERMY AND GALVANISM IN THE MANAGEMENT OF SEQUELÆ OF OCCLUSION, PARTIAL OR COMPLETE, AND OF RUPTURE OF THE CEREBRAL ARTERIES.*

BY EDWARD C. TITUS, M.D.,

AND

FREDERIC DE KRAFT, M.D.,

NEW YORK.

SOME time ago in an article read before this society and published in its official journal as well as the *International Journal of Surgery*, we reported on the use of diathermy as an adjunct in the treatment of chronic syphilis. In this preliminary report we showed that in these cases there was induced a marked heating of all the tissues, followed by active hyperemia, stimulation of metabolic processes and increased elimination, as evidenced by a greater amount of CO_2 in the expired air by local and general profuse diaphoresis, and augmented secretion of urine, both as to fluid and solids. Therefore the conditions produced in the tissues by this means are conducive to absorption of inflammatory deposits irrespective of their character.

As our later results proved equally satisfactory in various syphilitic manifestations, involving the brain and nervous system, the thought occurred to us whether diathermy could not be utilized to advantage in the treatment of cerebral conditions of non-syphilitic character.

Diathermy, by inducing an active and prolonged hyperemia in the tissues, increases the penetration of medicinal remedies to the affected structures, even to those in which the circulation has been impaired.

Our extensive experiments with galvanism have shown that it improves the nutrition of the coats of blood vessels as well as of the surrounding tissue, and beneficially modifies vascular tone. It will be thus seen that by the combined use of diathermy and galvanism effects are obtained which cannot be derived from the application of either of the currents individually.

During the past four or five years we have employed this combined method in many cases of cerebral disturbance, such as often precedes apoplectic seizures as well as for the purpose of removing as far as possible the results of cerebral hemorrhage or embolism, that is to say, both in the pre- and post-apoplectic stage.

*Read at the thirtieth annual meeting of the American Electrotherapeutic Association, Atlantic City, N. J., September 14, 1920.

Excellent results have been obtained by us in those cases of senile changes in the brain which often cause marked impairment of mental faculties, even though not always terminating in apoplexy.

There is a condition of the brain met with in subjects of advancing years which has variously been described as cerebral endarteritis, nervous breakdown, and cerebral neurasthenia, due to impaired nutrition of the brain because of deficient circulation.

This reduced blood supply is claimed to be the result of vascular changes, *i.e.* roughening of the vessel wall and narrowing of their caliber, with consequent deterioration of nerve elements. The same process may lead to thinning of the vessel walls with the production of miliary aneurysms. In these cases there is often a toxic factor, commonly of intestinal origin, although it may be due to impaired function of liver or kidneys.

Through accumulation of waste products a toxic irritability may cause vascular spasm, resulting in either anemia or hyperemia of portions of the brain, followed by venous engorgement of the area so affected.

This may lead to temporary paresis of one or more groups of muscles, chronic headache of variable character and location; to vertigo, double vision, tinnitus aurium, insomnia, loss of memory for recent events, changes in character and disposition. It is in just these cases that diathermy followed at the same sitting by prolonged use of the mild continuous or galvanic current applied to the head, together with appropriate medicinal and corrective hygienic measures, has shown the best results.

In post apoplectic conditions, whether produced by hemorrhage, thrombus, or embolism with their usual pathological changes, we cannot hope to improve the paralysis following the cerebral damage until attempt is made to repair the central lesion.

Diathermy followed by the mild continuous current to the brain, as will be described by my collaborator, Dr. de Kraft, is the best means we have found for this purpose. In the first place they will improve the general nutrition, increase elimination and give the patient a better outlook and hold on life. Secondly, by improving the local circulation they will aid nature in causing the absorption of extravasated blood and inflammatory exudate and will help to prevent the formation of cicatricial tissue or promote its absorption.

The writer has not deemed it necessary to give detailed histories of cases, but has left the clinical features to the members of this association who have had extensive experience, either with galvanism or diathermy.

Our sole aim has been to bring to your attention the advantage of combining both methods in the treatment of those cases which represent the subject of this paper.

Experiments conducted by Nagelschmidt on a head severed from a cadaver have shown that it is quite easy to heat the brain by means of diathermy. A thermometer was introduced through the occipital foramen in such manner, that the bulb rested in the middle line of a diameter drawn

through the temporal region. The application of a strong diathermic current, applied sideways through the temples, resulted in an elevation of 5° C. (approximately 10° Fah.) in five minutes.

That it is possible to activate the nerve, its cellular elements, would seem to be proven by another experiment conducted by Nagelschmidt on a living dog. A salivary fistula was made. The upper portion of the spinal cord was then subjected to the heat effect of a high frequency current (diathermy). A moderate current was employed for 10 minutes. As soon as a sufficient elevation of temperature had occurred, it was noticed that the saliva began to come in thick drops from the fistula. The production of saliva by the parotid, so acted upon, appeared to be greatly increased. It was also noted that the heat effect extended to the respiratory center. The animal executed the deep and rapid respiratory excursions characteristic of stimulation of the respiratory center.

Experiments on yeast cells have shown that the chemistry of the cell is increased by warmth. This may amount to an increase of 25 per cent beyond the normal functional activity.

When we apply diathermy to the brain in a living person, the effect is a complex one. We have, first, the influence of the diathermic heat direct on the brain cells. And, secondly, there is the effect on the blood coursing through the cerebral blood vessels, the adnexa of the brain and the bony covering, and the overlying skin, muscles, and fascia.

Whenever we apply a diathermic current to the brain or any other structure, we elevate the temperature by adding heat from without. This is accomplished without any expenditure of the subject's reserve material, without the wasting of any nerve force. As the result of this application of heat from without, the chemical interchanges within the cell are greatly facilitated and there results an improvement in normal function.

It is not at all necessary to use very strong currents in every case in order to obtain notable therapeutic effects. Frequently, a very slight elevation of the temperature of the part is all that is needed. Too great an elevation of temperature within the cranial cavity must be carefully avoided. For we might thereby easily impair, if not permanently damage, the delicate cells of the brain. Hence, our aim should always be to effect only a slight elevation of temperature. For through this we secure a secondary arterial hyperemia, augmented lymphatic flow, stimulation of cell chemistry, a tonic effect, improved vitality, and functional activity.

Personal experience with diathermy of the brain, dates back to 1907. Many times in the cases of backward children and in children suffering from epilepsy, there was a notable general improvement. This improvement manifested itself in brighter and more intelligent facial expression; in better personal conduct; in willingness to perform tasks given to them, or to study their lessons, as well as a gain in bodily growth.

It is quite possible that diathermy, in moderate dosage, has some stimulating, perhaps nutritional, effect on the hypophysis cerebri—the pituitary gland. It is true we have not as yet any very definite idea of the function of the pituitary body. We know that it may be linked with gigantism or dwarfism, with dystrophia adiposa genitalis. We know that the pituitary has much to do with gonad function. There is a strange relationship between the various glands of internal secretion; between the pituitary and thyroid and the sex organs. Derangement of one of these is likely to affect the other. It is not at all unlikely that improvement in function of the pituitary results from the vivifying action of high frequency currents applied in proper dosage to the brain. This explains the resulting general betterment of bodily function.

Diathermy of the brain is a new field to many. It is hoped that the foregoing remarks show the utility of using diathermy of the brain and cranial cavity in the conditions described. The technique found most suitable is as follows:—Have the patient recumbent, with the head carefully propped up on suitable pillows. Take a pair of electrodes of even size, 2½ x 3 inches. One of these electrodes is applied over the forehead, in the middle, just over the eyebrows, taking great care that the electrode is not too near the eyes. As the current follows the path of least resistance, proximity to the eyeballs would send the major part of the current through them. This must be avoided. The other electrode is placed just below the occiput over the cervical spine.

It is essential that a diathermic apparatus of a strength sufficient to assure a smooth current be used, and it must give no other sensation than that of heat. It would be most unsuitable to employ a current which gives even the semblance of the very slightest faradic effect when resistance, such as the cranium offers, is encountered. It is very necessary to direct attention to proper balance of the patient's circuit and that from the inside of the condensers and the spark gap. Remember, too, that no organ is so deeply seated that it cannot be reached by the vivifying warmth of high frequency currents. Proper attention to detail in their application will result in stimulation of cell function and of all glandular secretion. A careless technique without proper understanding of the activity we wish to establish will not give the results desired.

The current strength employed in the described method is from 200 to 450 milliamperes. The duration of the treatment varies with the degree of heat suitable to the case at hand and with the current strength employed. The aim should be to obtain a true physiological response and no more. Too much current, too long an application may be dangerous; or, if not, may nullify our efforts. Carefully watch the temporal blood vessels and the skin of the head and face. A slight swelling of the former and a slight flush of the skin indicates a physiological response. This is satisfactory. Carried beyond this point, vertigo, nausea, and faintness may be induced. The temperature of the surrounding air has much to do with the rapidity with which results are obtained. On a cold day, when the patient is chilled, it will take longer than on a hot, humid day.

As a general rule, it is best to employ the lower

current strength with a very moderate spark-gap, about 2 to 3 gaps on the de Kraft spark gap, for 20 minutes. Sometimes only a single gap is tolerable. Also, much depends on the size of the gap, and whether the spark gap is constructed of silver or tungsten disks. The thickness of the mica between sections of the de Kraft spark gap determines largely the voltage employed. In other words, it determines the length of the spark in the "A" circuit, and of the length of the oscillations in the "B" circuit—that is the patient's circuit. The silver disks give a slightly higher voltage than those of tungsten.

As we approach the subject of the application of galvanisation of the brain, we find that a good deal of work has been done in this line. Loewenfeld (*Centralblatt der medicinischen Wissenschaft*, 1881, page 132) reports some experiments on rabbits. After laying bare the membranes of the brain by trephining, he applied the galvanic current to the brain. He found that when the cathode was placed over the forehead and the anode over the neck, there occurred regularly a dilatation of the arteries of the meninges. When the arrangement of the electrodes was reversed, there occurred usually a constriction of the arteries. This observation tends to confirm the clinical observation made by many when treating purely functional conditions, such as neurasthenia and traumatic neurosis.

There was a period when much controversy arose as to the feasibility of causing the continuous current to overcome the resistance of the bony covering of the brain. As a matter of fact, it is quite easy to pass the current through the bones of the skull. If proof of this were needed, Leduc's experiments when a periodically interrupted galvanic current was passed through the brain of animals should remove all doubt. He succeeded in suppressing all cerebral functions in animals and in man by means of the above current. Dr. Louise Robinowitch gave a demonstration of Leduc's method before this society about 12 years ago.

It is hardly necessary to refer to the experiments of Fritsch and Hitzig. They showed that different convolutions of the brain are centers for the production of voluntary movements of muscles in different parts of the body. They removed the upper portion of the skull of a dog and found that, when certain portions of the anterior convolutions were stimulated by a weak galvanic current, movements were executed in certain groups of muscles on the opposite side of the body. These experiments show that there exist certain definite centers in the brain which regulate the movements of certain groups of muscles throughout the body.

If we pass a continuous current through the brain, laterally, from temple to temple, for instance, we find that even a very feeble current will produce dizziness, and there is a marked tendency to lean toward the positive pole. This dizziness varies with the current strength. When, however, we place one electrode in the median line over the forehead and the other over the occiput; or one over the top of the head, in the middle line, and the other over the epigastrium and then carefully and gradually turn on the galvanic current, no such effect is produced. This is of importance in our therapeutic applications.

Bartholow was among the first to suggest the utility of the continuous current in the conditions of the brain described. R. Remak, Erb, Bendict von Ziemssen, and others have shown that it is possible to obtain notable therapeutic results from cerebral galvanisation. Beard and Rockwell described a method which they called central galvanisation and found notable nutritional effects to follow its use.

The method, to be recommended as the one best suited for the treatment of the cerebral conditions herein described, is as follows:—An electrode, size 2 x 4 in., or 2¼ x 4½ in., is carefully moulded to conform to the contour of the forehead. Under this electrode, in direct contact with the forehead, are placed 30 layers of surgical gauze, saturated in salt solution. The gauze pad must be slightly larger than the metal electrode, so that none of the bare metal touches the skin. The electrode is then securely fastened over the gauze by means of a roller bandage; or, if this is not done, provision must be made to have the patient hold it securely in position. The patient lies on a suitable table while the current is administered. A second electrode, similar in size and construction to the one just described, is placed over the neck just below the line of the hair of the head. This electrode is held securely in position by a pillow suitably placed. Great care must be taken that the conducting wires are securely fastened to the electrodes and to the wall-plate or battery.

A word now as to the source of the current. A current obtained from a battery has proven the safest and most suitable for galvanisation of the brain. A well constructed wall-plate may also be used. This should have a voltmeter as well as a milliamperemeter; a means of regulating both voltage and amperage.

It is always advisable to begin with a very mild current; about 1 to 3 milliamperes and 5 volts. The reason for this is shown. At the beginning of the séance, uncomfortable sensations, even syncope, are likely to occur if the current is turned on too quickly. If the application is made with the patient in an upright position, an alarming faintness may ensue. Therefore, if the patient must sit up during the treatment, have him seated on a chair whose back can be quickly lowered, like the static treatment chair. As the treatment progresses and the current gradually finds its way more deeply, the current strength may be gradually increased to 10, then 20, and even 30 milliamperes.

As a general thing, the positive electrode is placed over the neck and the negative over the forehead. The usual time consumed for a thorough application is 30 minutes. When we wish to stop the treatment, it is *very* necessary to turn off the current very slowly and with great care. A sudden stoppage might cause unnecessary discomfort.

After such treatment, the patient's head should feel lighter. A few repetitions should result in a sense of general well-being, increased muscular

strength and improved mental processes. The results are better and more rapid, if this galvanisation is preceded by diathermisation of the brain, which seems to prepare the way for the galvanic current by reason of the improvement in the circulation. The better, more even, distribution of arterial and venous blood, as well as improvement in lymphatic flow favors a more even distribution of the galvanic current.

If a recent hemorrhage has occurred anywhere within the central nervous system, it would be manifestly unwise to begin the use of diathermy or of the galvanic current at once. Time should be allowed for the resulting acute process to subside. Paralyzed extremities frequently show disturbance of the circulation, such as edema, lowered temperature and cyanosis. They also show an imbalance of the musculature. This results from the fact that while certain muscle groups are paralyzed, their antagonists retain their normal function.

It has been found that the methods here advocated are sufficient, as a rule, to remove these after effects when combined with exercises of a re-educative nature. Under this heading may be classed such measures as static sparks, sinusoidal currents, etc.

Some recent experiments conducted by R. Ogden, and L. Franz (*Physiology* Vol. 1, No. 1) seem to show these results:

1. Animals in whom hemiplegia is artificially produced do not recover motor control if left to their own devices.

2. Recovery is rapid when treatment by muscle stimulation and nerve vibration is directed to the parts involved; and when special exercises to provoke the animal to move the paralyzed parts are given. When efforts are directed to the special nerves and muscles, and when the sound side of the animal is restrained so that climbing and feeding movements must be made by the use of paralyzed segments, improvement is rapid and recovery practically complete.

The conditions which we have earlier described have quite a different etiological base. The removal, as far as possible, of the central lesion, prepares the way for carrying out the suggestions contained in these animal experiments.

HYPOTHYROIDISM, INFILTRATION, AND HYPERTENSION.

By HENRY R. HARROWER, M.D.,

GLENDALE, CAL.

THE functional aspects of high blood pressure are being given increasing attention in current medical literature, and it is very clear that many members of the profession are coming to the conclusion that there is a fundamental underlying cause of the usual syndrome associated with high blood pressure that is not connected with hardened arteries, impermeable kidneys, or changes in the heart itself.

Quite recently a prominent Dutch internist lends emphasis to this particular subject in the following words: "We have no grounds for the assumption that high blood pressure is always secondary to heart, kidney, or vascular disease. It has no more significance than the discovery of a murmur or hardening of a normally soft organ. Because we can measure the blood pressure we have paid too much attention to it and hidden our ignorance behind the term 'essential hypertension.' The rise in blood pressure is merely one element of a morbid series which has to be regarded as a whole."[1]

Another recent interesting communication on the subject was made by Dr. L. F. Barker of Johns Hopkins at the last meeting of the Ohio State Medical Association.[2] He calls attention to the fact that high blood pressure appears to depend chiefly upon a narrowing of the lumina of the arterioles in the precapillary areas. It is believed to be, at first, functional and caused by hypertonus of the arterial musculature, but later on it assumes a partly organic character, the result of changes in the arterial walls. Barker believes that the different types of chronic arterial hypertension probably represent different stages in the development of the same fundamental process which may advance with variable rapidity and with variable associated involvement of cardiovascular, renal, cerebral, and other structures in different cases. This author then goes on to call attention to the general changes which are fundamentally responsible for the condition of high blood pressure, and he states that in order to prevent the development of this pathologic process underlying high blood pressure "one should first get himself well-born without constitutional inferiorities" and then should avoid intoxications and infections and live a well-balanced life, so ordering his activities that he can satisfy his physical, economic, social, educational, esthetic, and ethical desires in a well-balanced manner.

For many years it has been considered fundamental that toxemias favored high blood pressure and that they did so first by causing an over-activity of the circulatory system resulting in changes in the heart and blood vessels. Also that the toxemia irritated the actual glomerular tissue of the kidneys and, therefore, made changes which tended toward what the French have called "renal impermeability." Later our ideas have veered a little, and it is now considered possible and probable that irritation of the blood pressure raising mechanism of the adrenal glands, by means of the poisons produced in the alimentary canal and elsewhere, results in an increased activity of this pressor mechanism and in this manner produces a functional high blood pressure.

Be this as it may, there is no doubt that high blood pressure is merely a single manifestation of a serious comprehensive underlying change in the chemistry of the body, and it is proposed in this short paper to direct attention to one factor which has not been given the attention that its importance deserves and to connect it with the etiology as well as the treatment of functional or essential hypertension.

There have been a number of papers in the literature of the last five years calling attention to clinical experiences with the use of thyroid extract and other organ extracts as a means of reducing high blood pressure. A number of reports, includ-

ing that of Cummings of Los Angeles[3] and Bandler of New York,[4] speak highly of thyroid therapy as a means of modifying an excessive arterial tension. As far back as twenty years ago, before sphygmomanometry was developed, Eugene Hertoghe of Antwerp[5] called attention to the changes wrought upon the pulse rate and tension by the toxemia and disturbed metabolism of thyroid insufficiency, as well as from the opposite manifestation, or thyrotoxicosis. This intelligent pioneer student of thyroid function has emphasized the importance of the condition known as *infiltration* which accompanies various forms of thyroid insufficiency. Hertoghe's so-called "myxédème fruste"—a minor form of real myxedema — is always associated with changes in the nature of cellular infiltration. Hertoghe believes that the thyroid never can be functionally inefficient without there ensuing immediately an intoxication due to the deficient function in the cells themselves which is maintained by the hormonic "setting in motion" of the cellular chemical processes. They are unable to oxidize their foods and wastes and there follows an accumulation of poisonous substances which causes serious difficulty. In this connection it may be mentioned that Slosse of Brussels[6] credits the thyroid hormones with a "deaminizing" influence and he states that the deaminizing hormone of the thyroid is responsible for the oxidization of the precursors of the nitrogenous wastes of the body and there is good evidence to prove this physiologically and clinically.

At all events, this accumulation of cellular wastes brings about the condition which Hertoghe has called "thyroid infiltration" on well-known physical principles. We will presume that a given cell located in any part of the body—for the thyroid influence extends to every corner of the human organism—is not maintaining its normal chemical activities, that it is suffering with the condition which I have named "chemasthenia." The cellular activities are lessened and, as a result of this, the wastes of that cell are not prepared for elimination and remain behind. As a result of this there ensues an actual swelling of the cell due to the effort on the part of the body to maintain a normal osmotic tension. In other words, this increased osmotic tension in the cell draws fluids from other parts of the body, including the blood, lymph, and tissue juices, which evens up this tension and, therefore, extends the confines of the cell wall. We are in the habit of expecting an infiltration of the skin in myxedema, the very name of this condition indicates that there is an edema of the skin, and this edema or process of swelling or infiltration, as it is preferably called, is not limited by any means to the superficial tissues of the body.

It will be recalled that in Barker's paper,[2] from which a quotation already has been made, he believes that high blood pressure appears to depend chiefly on a narrowing of the lumina of the arterioles *in the precapillary areas*. What is the chief reason for the narrowing of these lumina? May it not be that the infiltrated cells which surround these prearteriolar canals or vessels are pressing upon the channels through which the blood usually flows, thereby reducing the circulation and also increasing the activity of the heart muscle which is necessary to force the blood through these finest capillary meshes? In this connection we recall very well that another of the commonest symptoms of hypothyroidism is a tendency to cold hands and feet. The circulation of the remoter parts of the body is very much below par, and this I believe to be due to exactly the same cause as the infiltration that already has been mentioned.

I think that we have reasoned out a relation between the infiltration of thyroid insufficiency and a decreasing of the size of the precapillary vessels and this I believe to be an important mechanical factor in the cause of hypertension. It is granted that the other toxic influences which would naturally accompany so serious a change in the general cellular chemistry must exert their influence also, and it is presumed that they do so through their effects upon the adrenal mechanism and its control of the circulatory muscular tone, including that of the heart itself. If we are successful in our thyroid therapy of the minor forms of hypothyroidism we will notice quite a change in this infiltration and its results. Many symptoms of a semimechanical nature are reduced. The cells are enabled to throw off a good deal of the effete material and there is a consequent increased chemistry as indicated by the urinary findings and a loss in weight due to the removal of much of the infiltrated effete material. This being the case there is a change in the nutrition of these infiltrated areas, and the skin (and other tissues) assumes a more healthy appearance; the work of the various organs, which heretofore have been puffy, soggy, and infiltrated, is more nearly normal; the circulation is increased and this mechanical factor, which I contend is a part of the cause of the high blood pressure, automatically is reduced.

In other words, thyroid therapy in cases of hypothyroidism with high blood pressure not merely removes a part of the accumulated toxema but at the same time favors a change in this mechanical obstruction to the circulation in these so-called "precapillary areas."

Many remarkable clinical experiences with both thyroid therapy and various pluriglandular formulas in the control of functional high blood pressure[7] has emphasized in my own mind a very important series of therapeutic possibilities in the treatment of this condition. It is first necessary to establish the fact that hypothyroidism is present and prominent as, for example, with my thyroid function test,[8] and then we have a most rational and scientific means of treating this particular condition; and if in conjunction with other benefits there is a change for the better in the high blood pressure then we are pleased. It may be said in this instance that another useful means of modifying functional high blood pressure due to toxemic irritation of the adrenals is the use of the antagonistic function of the pancreas which is known to balance adrenal medullary activity. We have had a good deal of experience in the use of combinations of thyroid with pancreas substance (not pancreatin) and many times the sphygmomanometer shows encouraging changes in the systolic pressure.

THE CLINICAL SIGNIFICANCE AND THERAPEUTIC INDICATIONS OF ABNORMAL BLOOD PRESSURE.*

BY A. S. BLUMGARTEN, M.D., F.A.C.P.,
NEW YORK.
ASSOCIATE ATTENDING PHYSICIAN TO THE LENOX HILL HOSPITAL.

THERE is no problem with which the practitioner is confronted that is more perplexing from the standpoint of both diagnosis and treatment than abnormal blood pressure.

Abnormal blood pressure occurs in a great many diseases and conditions—various infections, surgical conditions, etc., as well as in cardiovascular and renal disease. But it is manifestly impossible to discuss the entire problem in a short paper. Nor is the blood pressure the vital problem in these conditions. It is in patients who come to the physician suffering from numerous complaints such as headache, indefinite pains, sleeplessness, gastric symptoms, etc., none of which suggest the possible etiology of the symptoms, and the discovery of an abnormally high or an abnormally low blood pressure as the most striking, indeed often the only, objective finding, that the abnormal blood pressure presents itself as the vital problem. The persistence of this blood pressure in conjunction with the rather indefinite symptoms presents problems in diagnosis, prognosis, and treatment to the conscientious physician which are, to say the least, most puzzling. The patient, on the other hand, now suddenly become aware of the abnormal blood pressure, unconsciously calls to his mental aid the accumulated medical gossip of his friends and the abandoned lore of the profession in a vain attempt to obtain a prognosis as to his health and even as to life. He now looks to his physician with keen anxiety for a favorable answer to the many queries that he has conjured before him and for means to a rapid return to a normal sphygmomanometric status.

I shall therefore discuss the clinical significance of abnormal blood pressure only when it occurs as the important objective phenomenon in the light of the problems it presents to the physician and to the patient. To the physician the problems to be solved are: First, what is the significance of the abnormal blood pressure; secondly, how does it influence the prognosis as to health and life; and, thirdly, how can it be affected therapeutically? In the first place, before we can answer these questions, what may be considered the average blood pressure? For the normal varies within fairly broad limits. The blood pressure varies with the sex and age of the individual, the weight and height, the time of day, the posture, the emotional state, and probably also with numerous other factors. However, we may regard as normal a blood pressure of 120 systolic for an individual of about the age of 21 with an increase of 1 mm. of mercury for every two years increase in age. The diastolic pressure is normally about three-fourths of the systolic pressure, while the pulse pressure is usually one-fourth of the systolic pressure. This pressure is considered normal for an individual of average height, usually about 5 to 5½ feet. Variations according to height often amount to as much as 20 mm. of mercury for a minimum adult height of 3½ feet. A similar variation for the weight occurs with an increase of about 20 mm. of mercury for every 100 pounds of weight for the size and age of the individual. Emotional conditions, spastic states of various organs, posture, and other factors all play a rôle in determining the blood pressure, but these factors affect principally the systolic pressure, and the mean variations are usually anywhere from 10 to 15 mm. of mercury. However, it is not unusual in practice to see temporary variations amounting to as much as 40 mm. of mercury which do not indicate any pathology and which subsequently disappear. I have seen this condition frequently in definite endocrine syndromes. The diastolic pressure is more or less constant and not so subject to evanescent variations. Consequently it is of much greater clinical significance than the systolic pressure. We may therefore consider the blood pressure abnormal when there is a persistent increase or decrease of more than 15 mm. of mercury for the age, height, and weight of the individual.

The abnormal blood pressure is manifested by being either persistently high or persistently low. High blood pressure is much more common than low blood pressure. We must bear in mind that the high blood pressure is not a disease but merely a symptom. And its value as a symptom is dependent upon the primary or associated cause, of which the blood pressure is the important objective manifestation. Practically, the significance of high blood pressure in any patient is dependent upon three factors: (1) Whether there is evidence of renal disease; (2) whether there is evidence of arterial disease, and (3) whether the high blood pressure is the essential objective phenomenon. I do not believe it is always possible to differentiate or determine the associated or primary factors. Frequently the clinical picture is a composite one in which the essential or important factor is the objective hypertension in the course of which the associated phenomena occur. I am not including in this discussion the blood pressure changes in frank valvular heart lesions and in the course of infections, for in these conditions the primary lesion is so evident and the blood pressure changes are merely temporary indications of the functional capacity of the circulation or of the temporary reaction to a toxin, bacterial or otherwise, and it is these primary conditions that are the real problems.

Hypertension in Nephritis.—The persistence of high blood pressure readings with evidence in the

*Read at a meeting of the New York Physicians' Association, April 22, 1920.

urine of renal changes is one of the most frequent occurrences and presents many questions of diagnostic and prognostic import. The presence of albumin and casts in the urine in addition to the high blood pressure does not necessarily indicate a renal lesion. But when these findings occur in addition to the clinical syndrome of chronic nephritis with failure to concentrate the urine in the early morning specimens and evidence of functional disability as indicated by a low phenolphthalein output, and deficient elimination as shown by the Mosenthal test-diet and possibly by nitrogen retention in the blood, we then have definite evidence of renal disease with poorly functionating kidneys. But what relation does the high blood pressure in these cases bear to the definite renal picture? What is its rôle in the cause of the disease? What relation does it bear to the disturbed function of the kidney? And, lastly, what bearing has it upon the prognosis, and what guide does it offer in treatment? These are the perplexing questions that confront the physician. In attempting to solve these problems in specific carefully studied cases one is able to develop tenable hypotheses and very useful facts. In regard to the relation of the high blood pressure to the renal lesion, it is, of course, very difficult to determine which is the cause and which the effect. In many cases no definite etiological factor can be determined in the history; and even where such a definite factor exists it requires careful study to establish it as the cause of the renal lesion. However, the more we study cases of chronic nephritis very carefully the more do we come to feel that hypertension plays more of a rôle in the cause of the lesion than we had hitherto supposed. The work of Sir Clifford Allbutt and others has focused our attention more and more on the so-called essential hypertension or hyperpiesia. If many of these cases of so-called hypertension are watched carefully for a number of years it is found that they gradually develop vascular and often definite renal lesions with definite functional disability. Moreover, when a definite chronic nephritis is present, I believe the essential factor in the determination of functional disturbances of the kidney is rather the state of the renal-vascular system and the degree of hypertension. Careful study of cases of chronic nephritis with the aid of our modern functional tests and blood chemistry seems to show that there is rather a definite relationship between the degree of blood and pulse pressure and the functional ability of the kidney as indicated by the functional tests and the nitrogen retention in the blood. The higher the blood pressure and the lower the pulse pressure the greater is the functional disability of the kidney and the greater is the nitrogen retention. Furthermore, some of the highest figures of nitrogen retention and the greatest degree of functional disability may be seen in passive congestion of the kidneys in the course of a myocardial insufficiency which clears up with improvement of the primary cardiac lesion. Consequently, it is becoming more and more apparent that the evidence of the functional disability of the kidney, as shown by the functional tests and blood chemistry tests, indicates not so much the functional ability of the kidney, but rather a disturbance in the integrity of the renal-vascular system. On the other hand, the comparatively normal function of the kidney in cases of chronic nephrosis or so-called parenchymatous nephritis where the blood pressure is not increased certainly helps to corroborate this view. For in these cases the injury to the kidney is certainly extensive but the vascular system of the kidney is comparatively uninjured, and functionally such kidneys do very well. I have under observation now a young man of 28 who has had edema of the lower extremities and urine loaded with albumin for over two years. He passes enormous quantities of urine. His blood pressure is normal. All the functional tests of the kidneys show no evidence of disturbance, nor do repeated blood examinations show any nitrogen retention nor any change in the relation of the blood proteins. A careful physical examination on numerous occasions gave no evidence of arteriosclerosis. In spite of the fact that the cause of albuminuria in nephritis is unknown, we do know at least that it indicates a renal lesion. Here is a young man then in whom there is evidence of severe injury to the kidneys but who has a comparatively normal vascular system. He shows no functional disability of the kidneys whatever. Now if there is a relationship between the high blood pressure and the functional disability of the kidney it seems to me the persistent hypertension is of considerable ominous prognostic import in chronic nephritis; and consequently the high blood pressure ranks equally in importance with our modern measurable functional tests.

Since hypertension plays such an important rôle in chronic nephritis, the reduction of the blood pressure should and does produce a favorable therapeutic effect in chronic nephritis when the blood pressure is amenable to treatment. However, there is a wide gap between the problem itself and its solution, for the cause of hypertension in chronic nephritis has not been definitely established. While it is possible to modify the blood pressure experimentally by modifying the vascular tree, it is not so easy to do this in practical therapeutics. Personally I have not seen very great benefit from the use of vasodilators such as the nitrites, because spasm of the arterioles is certainly not the cause of hypertension in nephritis. The causative factors are probably definite chemical persistent pressor substances. I have obtained the best results by the use of digitalis and saline purgatives and the limitation of the fluid intake. Although benzyl benzoate has been strongly advocated recently for the lowering of blood pressure the results prove to be delightfully misleading. There is no question that in a number of cases in which we tried it the blood pressure was appreciably reduced, the urinary output was increased, and the nitrogen retention was diminished, and we became highly enthusiastic over the benzyl benzoate. While the cases were benefited sphygmomanometrically to an extent commensurate with normal variations accompanied by physical improvement, this was due to the postural changes more than to anything else; as all the symptoms and the high blood pressure began to return when the patient was allowed to be up.

High Blood Pressure and Arteriosclerosis.—The fact that the increase in peripheral resistance as the result of spasm of the arterioles causes a rise in blood pressure is responsible for the erroneous idea

that arteriosclerosis is invariably associated with high blood pressure. As a rule arteriosclerosis does not cause high blood pressure. The recognition of arteriosclerotic changes is dependent upon finding actual thickness of the palpable vessels and the resultant tortuous appearance of the visible ones rather than by the reading of the sphygmomanometer. We have no way of recognizing the thickness of the cerebral or visceral vessels. This we can only surmise by the evidence of cerebral and other visceral symptoms occurring when definite sclerosis of the visible and palpable vessels is present.

Clinically we can recognize two types of arteriosclerosis; namely, arteriosclerosis with hypertension and arteriosclerosis without hypertension. When hypertension is associated with arteriosclerosis it is important to determine which is the primary condition. Clinically we can differentiate two types of hypertension in arteriosclerosis. First, hypertension which is persistent and precedes the arterial changes. In all probability this is the case in the majority of instances that come under observation after the vascular changes have already occurred. We can only recognize these cases if they have been observed for years, but practically we seldom have such an opportunity. The arterial thickening in these cases is merely the compensatory effort to protect the vascular system against the strain of hypertension. The sclerosis of the vessels is soon followed by changes in the kidneys and other viscera. We therefore lay more stress upon the renal changes because they are readily recognized and measurable. Secondly, the cases in which hypertension occurs in the course of a vascular sclerosis. Here the associated clinical phenomena may indicate one of two conditions. In the first place hypertension may occur in association with vascular and cerebral crises, such as temporary aphasia, paresis of an arm or fingers, numbness, neuralgic pains, etc. The frequency, the extent, and even the occurrence of these crises determine the prognosis much more than the hypertension itself, since the crises are the danger signals of impending serious vascular calamities. On the other hand the hypertension may be persistent and be associated with albuminuria and casts. This is merely the indication of an early renal involvement. A high blood pressure is especially of great prognostic value in arteriosclerosis. The cases in which the hypertension is associated with vascular crises offer the most unfavorable prognosis, and the severity, frequency, and extent of these crises are always of serious omen. In the cases associated with renal changes the prognosis is determined by the severity of the renal changes and the functional ability of the kidney. Of the two types the arteriosclerosis with crises lends itself more readily to treatment. It is in these cases that the nitrites and other vasodilators produce the best results unless the atheromatous changes in the vessels are too extensive.

Essential Hypertension.—We are indebted to Sir Clifford Allbutt for focusing the attention of the profession on hypertension associated only with hypertrophy of the left heart but without vascular and renal changes. This type he called hyperpiesia or essential hypertension. The patients are comparatively young individuals and suffer from numerous rather indefinite symptoms which may be condensed into the colloquialism, "lack of pep," frequently associated with the usual gamut of neurasthenic symptoms. Indeed, many of these patients are mistaken for neurasthenics, and the older literature is crowded with remarks on the high blood pressure of neurasthenia, but careful study of this so-called neurasthenic high blood pressure proves that it belongs to Allbutt's group of hyperpiesia. Although Allbutt set them apart from the group of cases of arterial and vascular disease, subsequent and prolonged observation of these individuals over a period of years seems to indicate that this is merely the early stage of a definite vascular syndrome, the latest manifestations of which are the sclerosis of the vessels and finally definite renal changes. The condition occurs particularly in young men who take life seriously and work intensively. The sudden recognition of the high blood pressure is a sinister warning that they are traveling the path lined by vascular difficulties unless early aid is instituted and a rational modification of the individual's life begun.

Treatment, consisting principally of limitation of activities, of limitation and regulation of the diet, particularly the elimination of large quantities of food, and the occasional administration of vasodilators, usually produces good results. But we must be guarded in our prognosis as this depends largely upon the time when the patient comes under observation. It is unfavorable when more or less extensive cardiac and vascular changes have already developed.

Climacteric Hypertension.—I wish also to call attention to the group of cases of hypertension which is being more recognized in recent years. This is the form of hypertension occurring in women at the time of the menopause who come to the physician complaining of the numerous symptoms which are prevalent at this time. These patients usually complain of gastric and nervous symptoms, headache, palpitation of the heart, dyspnea, weakness, vertigo, etc. Careful physical examination reveals as the outstanding objective symptom a high blood pressure running as high as 200, 250, and even 300 systolic. At times there is found a slight enlargement of the heart, but in the majority of instances this is absent. These women are usually stout and of rather large stature. The discovery of the hypertension is a source of distress and worry to them and they imagine that they are in immediate danger of all the fatalities usually associated with hypertension and vascular disease. It is quite a problem even to the physician to explain the phenomena and to offer a prognosis. The fact that hypertension occurs coincident with the onset of the menopause indicates that the same factors are probably responsible for the high blood pressure and for the menopause itself. In other words the high blood pressure is merely the result of deficiency of the gonadal hormones. I shall not delve into endocrine phantasies to explain the condition, but it is apparently a symptom which evidently results from the effort on the part of the endocrine system to adjust itself to the new state of affairs incident to the menopause, and when the adjustment is complete the pressure is again lowered. The prognosis in the majority of these cases is good and they respond readily to treatment consisting of endocrine substances such as corpus luteum or ovarian ex-

tract, and particularly to the assurance that this hypertension does not indicate the expected vascular fatalities. However, careful and repeated physical examinations must be carried out to separate this type from hypertension with associated vascular or renal disease. The following is an illustrative case:

Mrs. H. D. consulted me about five months ago on account of severe pain on top of the head, pains in the back of the neck and a feeling of general depression following the onset of the menopause about five months before that. Examination revealed only a very large woman in whom the most important objective symptom was a systolic blood pressure of 205 and a diastolic pressure of 100. Repeated urinary examinations were absolutely negative and careful functional tests of the kidney were negative. Careful chemical examination of the blood showed no evidence of nitrogen retention. Repeated examinations during this time revealed only the same finding, namely hypertension without evidence of vascular changes. Consequently I concluded that the patient was suffering from climacteric hypertension. She responded, after assurance that the hypertension was not a bad omen, to regulation of the diet, limitation of the quantity of food, and the administration of corpus luteum for six or seven weeks. At the last observation her blood pressure was systolic 155, and diastolic 110.

The important problem in hypertension is of course always the etiology and I shall not discuss the infections, toxins, etc., that I believe probably do play a rôle in its causation. In each individual case it is very difficult to find these factors and, secondly, to establish their causative rôle. What is characteristic, however, is that the majority of individuals suffering from high blood pressure belong to a more or less characteristic type, although they do not all belong to the same type. They are usually serious individuals, intensive workers, tremendously energetic, and living well but not wisely, and usually attaining success at the expense of their vascular system. They are inclined to be obese, usually of rather tall stature, and take life seriously indeed; in other words living a life of tension which produces hypertension. When vascular changes are not too extensive, the gradual relaxation of the tension is rewarded by continued improvement in health and a relative reduction in the blood pressure.

Hypotension.—Abnormally low blood pressure is a comparatively rare condition as an entity. Of course low blood pressures occur in myocardial insufficiency, in anemia, tuberculosis, hemorrhage, acute infections, etc., but in these conditions it is a symptom of a well-defined and easily recognized cause. But I am considering hypotension as an entity with the absence of other definite etiological factors. Clinically several types may be recognized: (1) Hypotension in individuals who have always had relatively low systolic and relatively low diastolic pressure. Careful study of many of these patients reveals that they show characteristic endocrine stigmata, especially pituitary markings and acromegalic characteristics or characteristics which usually go with Froehlich's syndrome. The condition is probably some complex endocrine manifestation. (2) Cases suffering from fatiguability, headache, dizziness, with evidence of Sergent's white line; in other words, probably a condition of adrenal insufficiency. (3) A group of cases occurring in women in which the hypotension occurs suddenly, or gradually ushering in the menopause in which the low blood pressure is an associated phenomenon.

Low blood pressure as a rule is not of sinister prognostic import. Therapeutic results are difficult to obtain although numerous methods of treatment are tried. The most rational method consists in increasing the fluid intake and administering pituitary extract, thyroid extract, or ergotoxin. Usually, however, not any great benefit is obtained from any form of treatment. But one need not be discouraged by this, as few symptoms result from hypotension, and besides, hypotension in the majority of these cases is merely a long-standing stigma which is part of the individual and does not affect his health, his life, and his pursuit of happiness.

Conclusion.—I have endeavored in this brief paper to indicate the significance of abnormal blood pressure. When the blood pressure varies from the average, it is the hypertension that is mostly of clinical importance. I have attempted to emphasize its importance in those conditions in which the blood pressure itself is the dominating objective feature. Under those conditions its importance lies principally in its vital prognostic value in association with definite evidence of injury to the vascular system or to the kidneys. Without this associated evidence it is merely the pressure gauge of a life of tension except in those instances in which it records the effort on the part of the endocrine system to adjust itself to temporary discord. When not associated with vascular or renal phenomena and occurring in young individuals it is probable that the manifestation of hyperpiesia or of hypertension is largely produced by intensive living which in the majority of instances is followed by vascular and visceral changes, the most measurable of which are in the kidney.

Hypotension is merely an individual marking of an endocrine disturbance and may be regarded as an endocrine stigma.

Hypertension is amenable to treatment only in the absence of vascular or renal changes, and the best results are obtained by relaxation in everything, in work, diet, pleasures, etc. Medicinal substances are notoriously of limited value, but this does not mean that the condition is not amenable to treatment, for physical means, mental relaxation, outdoor exercise and regulation of the habits and diet afford more therapeutic aid than chemical substances except in cases of temporary vascular crises where the vasodilators are beneficial.

ERYTHEMA NODOSUM: ITS TREATMENT BY STREPTOCOCCUS VACCINE.

REPORT OF A CASE.

By SANDOR A. LEVINSOHN, M.D.,

BROOKLYN, N. Y.

Erythema Nodosum, as a clinical entity, has been but meagrely described in our standard textbooks on medicine and therapeutics. Osler mentions it only in connection with cerebrospinal fever and chorea. Forchheimer speaks of it passingly as occurring at times in association with gonococcemia. Jackson, in his "Diseases of the Skin," does make mention of it, referring to rheumatism, syphilis, systemic poisoning by infectious disease or autoinfection, as showing some causal relation to its

etiology, but without advancing anything very definite.

As far back as 1904 Abt[1] showed that a more frequent complication than rheumatism is endocarditis in association with erythema nodosum. The heart lesions, he says, may be considered infectious in nature, depending on the same cause which produced the erythema nodosum. He also states that Finger, who made a special investigation of the disease, came to the conclusion that it was the expression of a septic process. He found from histological studies that, aside from localized edema, round cell infiltration occurred in the centers and streptococci were present in the inflammatory tissue.

Hildebrandt,[2] in 1907, regarded it as quite possible, if not indeed proven, that one of the commonest forms of erythema nodosum, and, as he regarded it, indistinguishable from any other form, may be caused by the tubercle bacillus, yet an erythema nodosum need not necessarily be associated with tuberculosis.

The etiology of erythema nodosum has been brought forcibly to our notice by the work of Rosenow.[3] He definitely describes the pathology of the condition, with proof of having actually isolated from the nodules, a polymorphous diphtheroid closely resembling, in some stages, the streptococcus group, which organism he regards as the causative agent. Since then Stokes[4] has given an excellent description of the appearance of the lesions and a classification according to etiology of this rather uncommon condition.

According to Stokes, erythema nodosum belongs to the class of purpuræ. He divides erythema nodosum into two groups according to their etiology: (1) those due to tuberculosis; (2) those due to a streptococcus infection. Each of these has a characteristic appearance permitting ready differentiation.

The streptococcal nodes are larger, more edematous and brawny, more tense and hemorrhaghic, and may reach the size of a small palm. The tubercular nodes are smaller with a less marked peripheral reaction, the hemorrhaghic changes are less marked. In their place may be a purplish lividity, but usually only a well-developed erythema.

In the streptococcus type there is greater involvement of superficial tissues, the distribution is more apt to be over the front of the lower extremities, especially below the knees and over the front of the thigh, also around the large joints. The tubercular nodules are more circumscribed and deeper, they may appear on either front or back of the leg, but tend to localize posteriorly. They may appear in smaller numbers or in crops or groups, or one or two on the upper extremities or sometimes on the feet.

The streptococcus nodes show more marked color changes. The brown element is especially marked. They behave typically like a bruise. The tubercular node is pale at the onset, progresses from pink to livid purple or bluish tinge. If it persists, it remains bluish, softens, and may show a bullous surface or may undergo necrotic sloughing. The nodule may present only a mild erythema which subsides, leaving no color changes, or only a faint yellow stain, or there may be colorless ones among the erythematous nodes, suggesting Wende's nodular tuberculosis of the hypoderm.

A case came under my observation about nine months ago which probably belongs to the streptococcus group.

Case History.—The patient, Miss J., 23 years of age, bookkeeper, gave a negative family history. Previous to her present illness she had always been well except for various dental troubles. She had suffered some years previously from an apical abscess on one of her incisor teeth. This had been treated, after a great deal of procrastination, very conservatively, an attempt being made to cure the abscess without extracting the tooth. The crown was finally amputated, a porcelain crown being inserted by means of a pivot, the original root being left *in situ*. Many other caries were present, but all had received the attention of a dentist, most of the teeth being filled. She also had been subject to frequent attacks of rhinitis, probably accounted for by a deviated septum.

Several years previous to coming under my observation, Miss J. developed nodules under the skin over both tibiæ, and around both knee joints. These nodules came on rather suddenly without any referable cause. They varied in size from a ten-cent piece to an area 2½ x 5 inches in diameter. They were extremely tender and painful, red, hot, indurated and brawny, and produced an edema of the surrounding tissues which was tender and pitted on pressure. She went to her physician, who treated the lesions locally with what was evidently some form of ichthyol ointment and internally with salicylates. This afforded her very little relief, but after several months the lesions for the most part disappeared, and in disappearing, left black and blue discolorations, behaving exactly like so many bruises. Since then, until a few months ago, she would develop, on and off, the same nodules, which would alternately become worse and then improve, but never entirely disappear.

About nine months ago this patient came to me with her right leg swollen from knee to ankle. This swelling was due to the confluence of several of these large nodules with surrounding edema. Several small nodules also were present around the left knee. This was the worst attack she had ever had and she now experienced difficulty in walking because of the pain, and could not wear high shoes.

In consultation with Dr. Louis G. Shapiro of Paterson, N. J., it was decided that she was suffering from erythema nodosum, from its appearance probably of streptococcic origin. Physical examination was otherwise entirely negative. There was no evidence of tuberculosis. The tonsils and sinuses were negative, and aside from the teeth, all possible foci of infection were excluded. The patient had just had a lot of dental work completed, and although dental radiographs were advised, they were not taken.

Treatment.—In view of the failure of the customary drug treatment, it was decided to put the patient on vaccine treatment. For this, an ordinary stock vaccine containing 800 million streptococci and 400 million pneumococci in each cubic centimeter was used. On November 1, 1919, I began with an injection of .2 c.c. of this vaccine. The next day Miss J. developed a swelling of her arm at the point of injection, but no other symptoms. The swelling and pain in her arm became more marked during the next few days and then gradually disappeared. No effect was demonstrable on the leg lesions. November 15, 1919, another injection of .3 c.c. was given in the other arm. The local reaction was now much more pronounced, and following this, the nodules on her right leg became more discrete and the edge of the tibia could be felt superficially between the nodules, whereas previously, this entire area had been edematous. November 30. 1919, another injection of .3 c.c. was given. The results were about the same, the nodules showing but very slight improvement. December 15, 1919, .5 c.c. were injected. The next day Miss J.'s arm became very much swollen, very red and painful. The reaction was so intense that I thought I had produced a suppurative process by the injection. The leg lesions also became very much aggravated. No systemic symptoms were present, but the arm was

sufficiently painful to keep Miss J. from her work and to require wet dressings.

It was more than five weeks before the effects of this injection disappeared. At the end of that time, at the point of injection, a nodule exactly similar to those over the tibia was present, with some black and blue discoloration in the overlying skin. The leg lesions had quieted down somewhat and were now in just about the same condition as they had been previous to the .5 c.c. injection.

It was decided to begin the injections again, but this time I started on February 1, 1920, with an initial dose of .2 c.c. This resulted in slight soreness of the arm with the production of a nodule at the point of injection, but with marked improvement of the leg lesions, the nodules becoming smaller and less painful. February 15, 1920, .2 c.c. of vaccine were injected. Another nodule was produced at the point of injection, but all pain in the leg now disappeared and only two or three small discrete nodules remained, not tender except on deep pressure. March 1 and March 15, two more injections were given, each time, .2 c.c. Each injection produced a typical nodule at the point of injection, which, in time, disappeared.

The improvement after this was steady and continuous. The leg lesions have entirely disappeared, not a semblance of a nodule remaining. This is the first time in four years, *i.e.* since the onset of her illness, that she has been entirely free from these nodules. During the last four months she has received no injections and has shown no signs of recurrence. It is now over three months since the last nodule disappeared.

Comment.—Erythema nodosum is a chronic, low-grade infection secondary to a primary focus elsewhere. The primary focus is not always readily demonstrable. As a matter of fact, it may have disappeared at the time the patient appears for treatment. It is generally accepted that all possible foci of infection should be removed, but this is frequently a difficult task and necessitates the removal of teeth, tonsils, etc., without always accomplishing the desired result, much to the chagrin of the physician.

Consequently streptococcus vaccine was used with the hope for an efficacious action because of the chronicity and low grade of the infection.

The local hyper-reaction resulting from the treatment, and the production of nodules at the site of the injections, resembling the nodes over the tibiæ, suggest the specificity of the streptococcus for this lesion.

The vaccine treatment of erythema nodosum gave a gratifying result in this instance. It is recorded with the hope that it will be tried by others.

Hemophilia in Women.—The existence of hemophilia in the females of bleeder families has always been denied. Bucure, to test the matter, collected notes of all the alleged female bleeders in literature, 202 in number. Of this number not one stood a careful investigation. Incoercible hemorrhage is not hemophilia, nor is the latter a mere synonym of the "hemorrhagic diathesis." In general, gynecological hemorrhages in women are of constitutional, local, or ovarian origin.—*Schweizerische medizinische Wochenschrift.*

Medicolegal Notes.

Insufficient Proof of Loss of Vision.—In a proceeding for workmen's compensation, where one report by physicians and specialists gave the loss of vision of the workman as 50 per cent. and another at 90 per cent., and there was no report as to whether the vision could be corrected by the use of glasses, an award for total loss was set aside and the matter remitted to the Industrial Commission for further consideration on account of the unsatisfactory state of the record.—Cortina v. Lathrop & Shea Co., 180 N. Y. Supp. 855.

Practice of Medicine Without License Not a Joint Offense.—The Springfield Court of Appeals, Missouri, in a proceeding against two defendants charged in the information with practising medicine without a license, held the information bad for the reason that the practice of medicine is not in and of itself a crime, and that it becomes a crime in Missouri only through a personal default of the defendant who does not secure a license from the state board of health. It is a strictly personal offense, and not one that could be a joint offense.—State v. Mitchell, (Mo.) 219 S. W. 977.

Reading Medical Text-Books on Cross-Examination.—In a personal injury action it was held that the trial court did not err in allowing the plaintiff's counsel to read extracts from a medical text-book in framing his questions on cross-examination of a physician, who had stated that the author was an eminent authority. The reason for permitting such reading on cross-examination is to test the learning of a witness who testifies as an expert. This could not be done if the questions were required to be such as to conceal the fact that they were based on such approved text-books. The fact that the jury always knows that counsel is reading from the text-book in asking his questions is held immaterial.—Ganz v. Metropolitan St. Ry. Co., Missouri Supreme Court, 220 S. W. 490.

Negligence in Setting Fracture Not Established.—In an action by a laborer against his employer, a lumber company, for alleged malpractice of a physician employed by the defendant company in treating the plaintiff's right leg, which was broken between the knee and the thigh, resulting in shortening it by 2½ inches, the plaintiff testified that the physician tied a straight board to the outside of the leg, tying it with string and bandages and that no weights were used. He was corroborated by four witnesses. Five physicians testified for the plaintiff that it was their opinion, as experts, according to the testimony they had heard, that the treatment accorded was unusual and inefficient; that a complete anesthetic, such as chloroform or ether, should have been used, and that the hypo injection of one-half grain of morphine and one-hundredth grain of hyocine administered was insufficient.

The physician denied the statements of these witnesses as to his treatment of the case. He testified that he had used the Linton splint of three boards. He was corroborated by the employer's carpenter, who made the splint for him. This witness testified that the physician drew the plan of the apparatus; that the witness constructed it in half an hour and that he assisted the doctor in adjusting it to the plaintiff's leg. Three physicians testified for the defendant that a complete anesthetic was not always necessary in treating a broken femur, that it largely depended on the patient's condition, and that the physician in attendance was the best judge of whether relaxation of the muscles had taken place or not. They were of the opinion that the administration of morphine and hyocine was sufficient in some cases. They also testified that the use of the Linton splint was general throughout the hospitals in connection with a broken femur, and that it was used without weights. The plaintiff's leg was measured, and, instead of being 2½ inches shorter than the left leg, it was found to be practically one inch shorter; and it further appeared from the evidence that with the most skillful treatment the shortening of an inch, or an inch and a half, might occur. It could not therefore be held that the shortening was due to the fault, neglect, or lack of skill of the physician in defendant's employment, and judgment for the defendant was affirmed.—Ayala v. King-Ryder Lumber Co., Louisiana Supreme Court, 83 So. 799.

THE KIDNEY IN PULMONARY TUBERCULOSIS.

THE kidney is normal in the majority of cases of pulmonary tuberculosis, but the principal lesions that this organ may present are amyloid degeneration, chronic nephritis and acute morbid processes. During the evolution of pulmonary phthisis amyloid degeneration will first develop in the liver, spleen and suprarenal capsules before attacking the kidney, and it is not uncommon to find a massive amylosis of these viscera while only a few glomeruli and some arteriolæ of the pyramids will offer an amyloid infiltration. At this phase of the process, excepting in cases where some chronic renal lesion preexists, there usually is no clinical symptom of nephritis and only an albuminuria or a polyuria will occasionally direct the physician's attention to the kidney.

In these cases, a study of the urinary secretion will reveal a most peculiar syndrome; on the one hand there is a considerable drop in Ambard's coefficient, and on the other, in spite of a sufficient chloruria, the percentage of the chlorides of the serum is below the level of normal secretion. It is consequently to be supposed that these signs indicate an exaggeration of the renal power of concentration—a kind of hypersecretion. When a histological examination can be made in good conditions, a peculiar hypertrophy of the cells of the tubuli will be found, which seems to be the histologic evidence of hypersecretion.

From the practical standpoint, this urologic syndrome in a tuberculous subject should lead to the diagnosis of amyloid degeneration of the kidneys before the advent of extensive edema, massive albuminuria and incoercible diarrhea.

An ordinary Bright's disease may be met with in pulmonary tuberculosis and usually the inoculation of the urine or a bit of the renal tissue will remain negative, but a positive result is not in itself sufficient to regard a vulgar nephritis as due to the bacillus of tuberculosis. A syndrome of nephritis may depend upon certain tuberculous infiltrations of the kidney—real follicular nephritides. Finally, Koch's bacillus may provoke certain atypical lesions of the kidney, such as a secondary sclerous reaction invading the tubercle, or an interstitial infiltration which, from the onset, is unlike the classic follicle.

In the kidney the connective tissue reaction is much more common. The sclerosis forms local cicatrices which for a long time are infiltrated with round cells and in which the presence of the tubercle bacillus can be demonstrated. The remainder of the cortex, even the areas adjacent to the tuberculous lesion, remain intact for a long time. In those cases where the most extensive lesions have produced the syndrome of both chloride and nitrogenous retention, this special character of tuberculous sclerosis will also be found, and given these data, it is unlikely that the tubercle bacillus can be incriminated in ordinary Bright's disease of tuberculous patients.

Koch's bacillus can provoke acute generalized lesions of the kidney under peculiar circumstances, but two elements are necessary for their production. On the one hand, a subject in the state of allergy, sensibilized for certain doses of antigen by the infection of the first inoculation which he has received—such is the case of the phthisical subject; on the other, a massive reinoculation of Koch's bacilli by way of the blood and also, perhaps, by its soluble toxins, an acute reaction to tuberculin being manifest. Such a bacillemia suddenly occurring may cause death without hardly any clinical reaction and it alone can explain the generalized acute lesions of the kidney, lesions paradoxical in appearance found at autopsy of certain cases of chronic pulmonary tuberculoses. Some instances of terminal acute nephritides represent the same pathogenesis. A less intense allergic reaction likewise undoubtedly explains certain acute hemorrhagic nephritides of a temporary kind that clinically represent a true Koch's phenomenon in the kidney.

THE PROGNOSIS AND COMPLICATIONS OF DIABETES INSIPIDUS.

GENERALLY speaking, it cannot be said that diabetes insipidus is a serious affection, although it has been compared to the mellitus form as far as its gravity is concerned. Symptomatically, diabetes insipidus gives rise to little disturbance other than some lassitude and pain in the renal and epigastric regions. On account of their incessant thirst and desire to micturate these subjects develop insomnia and a peculiar hypochondriacal state. The body weight rarely decreases in any notable degree.

In some cases the disease develops suddenly, while in others its onset is slow and announced by premonitory urinary disturbances. The affection is frequently encountered shortly after birth, and most observers believe that this congenital polyuria is far more serious than that occurring in the adult. In the young the normal development is interfered with because the disease causes a considerable loss of nutritive material, and because of the loss of vitality that ensues the child is unable to offer serious resistance to the common diseases of early life. Roger believes that polyuric children rarely live more than from three to nine years; others maintain that a polyuria commencing in adult life is more serious than that of childhood. But it is

nevertheless certain that death is common in the young and infrequent in adults. Some cases, although few, have been recorded of complete recovery from diabetes insipidus in childhood, but the subsequent histories showing that the cure was permanent are lacking.

One of the characteristics of diabetes insipidus is to improve for a time and then later on return. After several paroxysms of acute polyuria the daily amount of urine may drop to two or three quarts, but upon the slightest occasion, usually for some unknown reason, an increase of the diuresis takes place. The alternatives of amelioration and recurrence are often related to hysterical polyuria.

There is one form of diabetes insipidus which usually is recovered from, namely, when it is of traumatic origin, if the injury is not severe, and in which case it may not last for more than two or three months. Otherwise, the affection will persist. The same is true of diabetes insipidus resulting from acute or chronic intoxications; it invariably recurs in such cases. The most tenacious forms of this disease occur with cerebral tumors or other brain lesions, but it is to be recalled that syphilitic polyuria will disappear by appropriate treatment. Briefly put, diabetes insipidus may be recovered from, but more frequently only a temporary amelioration results, to be followed after a variable length of time by renewed attacks of polyuria. The affection accompanies the patient to the threshold of old age, but definitively disappears at about the age of sixty.

Complications are less to be feared than in diabetes mellitus, and intercurrent affections sometimes seem even to have a favorable influence on the evolution of the polyuria syndrome. Thus, acute affections often cause a drop in the urine to the normal daily output, which lasts as long as the acute disease. As soon as apyrexia occurs the diuresis rapidly assumes its previous course. At other times the polyuria is not influenced by high temperatures like that of scarlet fever, smallpox, etc. Pulmonary phthisis, regardless of what some observers have said, is a rare complication of diabetes insipidus, but it must not be forgotten that a polyuria may be a symptom of tuberculous infection. Pulmonary tuberculosis as a cause of death in diabetes insipidus is quite exceptional, since Lanceraux met with it in only two cases out of a total of seventy cases of diabetes insipidus under his care. Occasionally, diabetes mellitus may complicate the insipid type, but in these circumstances the amount of sugar eliminated is small and does not darken the prognosis. Cases of alternating diabetes mellitus and insipidus have been seen in the same subject or in one or several generations.

What really aggravates the prognosis of the polyuria is its tendency to be transmitted by heredity, especially when it has a nervous origin. However this may be, it can be said that diabetes insipidus is not a serious process *quoad vitam*, but it is a disagreeable infirmity, giving rise to nervous depression and hypochondriacal ideas.

THE ETIOLOGY OF OSTEOSARCOMA OF THE UPPER JAW IN CHILDREN.

THE history of sarcomatous growths in childhood is not old, especially of those of the bones. Schwartz of Paris, out of a total of one hundred and seventy cases, found three between the ages of one and ten years and forty-five between the ages of ten and twenty years, so that from these figures it would appear that late childhood and adolescence pays the larger tribute. Among the bones of the skeleton, the jaws hold an important place, if not the foremost, and out of one hundred cases of malignant neoplasms in children Picot found seventeen cases of tumors of the maxilla. Finally, Roger Williams has collected seven cases of sarcoma of the upper jaw, two of which were congenital, one in a child three years and a half old, two between the ages of ten and fifteen, and two in subjects over fifteen. Briefly, sarcoma of the upper jaw is more common in childhood than is generally supposed, and this fact was pointed out by Letailleur in his thesis (Lille, 1895), although it seems to have passed unnoticed. This relative prevalence in childhood may be accounted for to a certain extent by the developmental phenomena of the upper maxilla. Highmore's antrum, formed by the spreading of the osseous laminæ composing the upper jaw, does not exist in the fetus, but appears during early infancy and gradually develops. During this time the bone is the seat of a kind of physiological hyperemia related to the process of development of the osseous walls which favors the formation of neoplastic tissue. From the viewpoint of sex, these malignant growths differ from what is met with in adults. It is generally supposed that cancer in general is more common in the female, but during the first years of life the contrary holds true. As to the cause of these neoplasms it is no better understood in children than in the adult. In the first place, a previous injury is probably too often invoked to explain the production of the neoplasm, but in some cases it has distinctly acted as a real provocative agent in determining the localization of the growth.

Out of one hundred cases collected by Estlander, the left side of the upper jaw was the site in seventy, but why this should be so is not at all clear. In some cases the neoplasm has started around a deviated tooth or one that was in bad condition, or an ectopic tooth. The question of heredity, so much discussed in the case of malignant growths in general, is perhaps still more doubtful when childhood is concerned. Saint-Germain believed that heredity could be absolutely ruled out of the etiology of malignant growths in children, while a no lesser authority than Hutchinson professed an entirely contrary opinion. There are unquestionable instances in which heredity appears to play a distinct part in the constitutional foundation of the cancerous tendency, but in most instances it cannot be invoked.

The congenital origin of these sarcomata is of the utmost infrequency; however, there are two authentic instances of these growths in the upper

maxilla reported by Roger Williams. There are other factors which may have some influence in development of osteosarcoma, although this is not clear; such as the nationality, the rheumatismal diathesis, and syphilis. However this may be, it is evident that the distinct origin of sarcoma of the upper maxilla in children cannot be clearly accounted for. But one thing is certain, and that is in all the reported cases the growth in the upper jaw was not noticed until it had attained a certain degree of development, and thus nothing in the patient's antecedents in the way of predisposition could be ascertained with certainty.

CANCER AND MARRIAGE.

DEELMAN, chief of the laboratory of the Amsterdam Cancer Institute, reports some data on this subject in *Gynécologie et Obstetrique* for June, 1920, i, 6. The locations of cancer studied were the cervix and corpus uteri, breast, liver, and stomach. It is of interest to note that these studies were begun by the late Professor Treub and finished at his request by the author. The material all came from Amsterdam. In cancer of the breast the investigator should always note the number of children, the duration of lactation and the presence of mastitis. But as for being able to show any connection between these functional activities and the incidence of cancer it must be stated that cancer has no proved connection with the functions of the breast. The declarations of authorities on this relationship are negative or not pronounced. The author has studied records of breast cancer deaths in Amsterdam since 1862. Unfortunately the number of children borne by the women had not been recorded. Of 531 breast cancer deaths taken for analysis it was found that 428 patients were married, while 103 were single. But the number of married women greatly exceeded that of the single so that the marriage state alone cuts little figure. Study by decades, however, taking into account the ratio of married to single, shows plainly that the single woman after the age of forty is somewhat more predisposed than the married. Before that epoch the conditions are reversed. Hence the function of the breasts favors the appearance of the disease. Sanders has obtained the same results in Rotterdam. Fibiger in Denmark finds cancer of the breast relatively more common in the single, but no age periods are stated. Figures obtained from Stuttgart and from the whole of Bavaria support the author. Cancer of the uterus was found in 504 cases to be much more common in the married, this holding good for the period after as well as before forty. There is therefore a contradiction between uterus and breast figures. Here we have figures which cover the number of children born. Opinions from older literature were to the effect that the more children the greater liability to cancer. This is the result arrived at by Hoffman. Penris, a Hollander, has compiled a ratio between average births and average age for cancer of the portio. But 4 per cent. were nulliparous and apparently the number of children did not increase with the incidence of cancer. In Amsterdam cancer of the cervix and corpus are aggregated together in the statistics. About 10 per cent. as a rule are cancers of the body, and in the author's material it was found that the percentage was eight. The nulliparity of women with cancer of the body was found to be six times that of those with cancer of the cervix. The corpus cancers also occurred at a considerably later period, and, as stated, by preference in nullipara. Cancer of the stomach and liver in women occurs more frequently in the married. The number of children is not a factor in the production of any kind of cancer.

THE MORAL ELEMENT IN DIAGNOSIS.

THE belief that men bring on, or contribute to, their own ailments is common enough among moralists and cynics, and many questions come up in practice in which the patient's responsibility for his own condition is bitterly argued. Fortunately the business of the true physician is to cure his patient first, although he may preach to him or scold him afterwards to scare him into abandoning his injudicious courses. Aside from such subjects as alcoholism and drug addition the question of responsibility comes up very freely. As is stated by Ley in *La Presse Médicale* for August 28, 1920, xxviii, 61, no one accuses a patient with harelip or tuberculous kyphosis of bringing on his condition deliberately. But if an adenoid subject persist in holding his mouth open he may be accused of contributing to this habit by the layman and even some medical men. If he is a nail biter he will lay himself much more open to accusation, as will also be the case in nocturnal enuresis. Thousands of subjects accused of moral inertia have been shown to be suffering with the hookworm. Certain cases of onanism are due to irresistible impulses, and scores of psychopaths—habitual liars, kleptomaniacs, etc. —are clearly irresponsible, for one or another reason, to say nothing of hystericals and epileptics. No doubt many a paretic in his early stages has been scolded and abused for his moral delinquencies. We once attended a medical meeting in which a member in the beginning manic phase of manic-depressive insanity treated his fellows with contempt, abuse, and sarcasm; yet of all this body of intelligent practitioners not one realized the condition of the man, and many of them indulged in bitter criticism of his conduct, both to his face and after he had left the building.

PALILALIA AND PALIKINESIS.

ECHOLALIA in the strict sense of the term implies that the subject echoes the words of the speaker, while in palilalia the subject repeats his own short answers to questions. The expression palilogy means that an orator repeats himself for the sake of emphasis. Palikenesis is the repetition of a gesture several times, and among the gesticulating races must be closely related to palilalia. In the latter the words repeated are usually short and the custom does not extend to repetition of groups of more than two or three words. The reviewer knew of a subject with cerebral hemiplegia who was apparently in good mental condition; upon being told a

piece of news he would reply three times in succession "Is that so?" This peculiarity attracted no attention from the laity, who evidently regarded it only as a mannerism, yet it was evidently palilalia. In an article by Schulmann in *La Presse Médicale* for Sept. 22, 1920, xxviii, 68, the case is related of a woman of 76, a hemiplegic, who looked after herself very well although her mental powers were clearly diminishing, whose most pronounced symptom was palilalia with palikenesis. If asked how she was the reply was "Not well, not well, not well," and when asked her occupation repeated five times the word "flowers." If a word provoked a pleasurable emotion it was repeated more often than one without that suggestion. A gesture to indicate the act of scratching in describing the pruritis from which she suffered was repeated many times. Many of these subjects have pseudobulbar paralysis, but this could be excluded in the case in question. The palikenesis naturally suggests tic-like movements, and like certain tic subjects these patients may weep and laugh in purely spasmodic fashion.

Pancreatic Dyspepsia and Its Coprological Syndrome.

THE statement is occasionally made today that pancreatic preparations when given therapeutically are destroyed in the stomach, and this despite the fact that practically all writers on pancreatic insufficiency prescribe these remedies and prescribe them to the exclusion of all others, and often do not even allude to destruction. In addition we have seen many statements of recent years which imply that these remedies are not inert. We recall the statement that pancreatin will raise the opsonic index and in these experiments the drug was not even given in capsules, but, if we remember correctly in compressed tablets. During the period of interest in the antitryptic index and its clinical application we recall the statement from responsible clinicians that cancer patients gained in weight when pancreatin was given and lost it when the remedy was suspended. In fact, the claim that pancreatin is inert when taken by the mouth has never been fairly substantiated, while clinical experience is to the contrary. In the gastroenterological number of *La Médecine* (July, 1920, i, 10) Cade contributes an article on pancreatic dyspepsia as diagnosticated by the coprological formula—for clinically the symptoms are not typical. Negative finds do not exclude pancreatic dyspepsia. Insufficiency is by no means necessarily due to organic disease and may be functional. The tests enumerated to determine the coprological syndrome are too numerous for citation here, and nothing new is quoted. Under the head of treatment the sole mention is that organotherapy is sometimes successful. The author does not refer to the recent reports on the treatment of alimentary anaphylaxis by pancreatin.

Cure of Oriental Boil by Emetine.

THE conquests of chemotherapy have largely been made among tropical maladies and with the organic arsenicals, antimony, and emetine. At present it may not be possible to speak finally of the spirillocide, trypanocide, or analogous properties of these substances, for the curative action may be an indirect one. But for the time being a direct parasitotropism may be inferred. In *La Grèce Médicale* for June, 1920, xxii, 6, Photinos relates the cure of 23 cases of Oriental boil through local injections of emetine chlorhydrate. This series of cases is tabulated in detail. The average case requires from 15 to 30 days to cure it and the number of injections varies from one, as a rule, to a large number in advanced cases with multiple lesions. The author is satisfied that the drug acts directly on the *Leishmania tropica* or parasite responsible for the disease. As a rule one injection, as stated, answers the purpose, the actual amount of drug injected being from 0.01 to 0.05 gm. The diagnosis must, of course, be first made by microscopical study of blood drawn from the lesion. To obtain favorable results with such small dosage the lesion should be single and not larger than a silver franc piece. The necessity for prolonged treatment with indefinitely repeated injections appears to be due wholly to inability of the solution to reach the parasite. Spontaneous cure may be eliminated in these cases for this occurs only in cases of long standing in which the disease seems to have spent itself. At least a year must have elapsed before we can expect this termination, and as one of the names of the affection is the "one year button" this signifies that the untreated button pursues a chronic course by nature, spontaneous recovery being, of course, very unusual.

Diagnosis of Granuloma Malignum.

UNDER this term Pesce gives a systematic account of Hodgkin's disease and allied conditions in which leucemia is absent, in the *Revista Sud-Americana* for August 15, iii, 8. His remarks on diagnosis may be reproduced. In the first place we have no sure-fire resource and can only suspect its presence when we have ganglionic enlargement, fever, cutaneous manifestations, and a certain blood state. But both fever and skin lesions are often absent, and when present without characteristics while the blood picture varies, the most significant features being lymphopenia, eosinophilia, and myelocytosis. We must depend mainly on exclusion of a large number of granulomatous and neoplastic affections. The author adds his opinion that the morbid process is purely inflammatory, of unknown origin, having no characteristic blood formula, pursuing a chronic course, and destroying life by cachexia plus anemia. There is no efficacious treatment save the *x*-rays. The author reports five personal cases seen in the Italian Hospital at Buenos Ayres, both cervical and inguinal types being represented, the former being in part associated with axillary lesions. Two of the five subjects presented a positive Wassermann reaction.

News of the Week.

Foreign Doctors Invade Spain.—Foreign practitioners, particularly Austrians, have invaded Spain in such numbers that native physicians and surgeons have appealed to the Government to make regulations making it obligatory that foreign practitioners acquire a medical degree in Spain before being permitted to practise.

To Study Conditions in Europe.—The National Information Bureau has sent its Director, Mr. Barry C. Smith, overseas to make a special study of American relief work in Austria, Serbia and Poland. His investigations will make available to the members of the bureau an up-to-date estimate of the relative importance and efficiency of the various agencies abroad which make appeals for funds. It is expected that a flood of new appeals will be coming over, especially from American relief organizations operating in Eastern Europe.

Relief Workers Sail for Near East.—A party of men and women, members of the Commission for Relief in the Near East, sailed on the *Pannonia* last week, bound for Turkey and other parts of Asia Minor. Dr. Russell P. Uls of White City, Kansas, who was one of the party, will open a trachoma clinic in Constantinople.

Anti-Tuberculosis Vaccine.—It is announced in the daily press that Dr. Calmette and his colleagues of the Paris Pasteur Institute have discovered an anti-tuberculosis serum for cattle. They are reported as believing that they are on the right track to develop a vaccine that will prevent and cure tuberculosis in man.

Typhoid Epidemic in Ohio.—The water system of the town of Salem, Ohio, is held responsible for an epidemic of typhoid fever which, up to Nov. 13, had totaled 762 cases, with ten deaths. A sanitary survey was made by State and Federal officials, and recommendations were made for changes in the water system.

Warnings and Legislation Against Horsehair Shaving Brushes.—Surgeon-General Cumming of the United States Public Health Service, has just issued a fresh warning against the use of horsehair shaving brushes, to which not a few cases of anthrax have been traced. The Public Health Service has made every effort possible under existing laws and regulations to prevent the occurrence of anthrax due to infected shaving brushes, but in spite of its efforts anthrax cases occur and will continue to occur unless the public ceases to buy and use horse-hair brushes for shaving, according to Surgeon General Cumming. Congress at the next session will be asked to prohibit the use of horse-hair for that purpose. It is doubtful, however, if any effective measures can be taken by health officials to curtail the use of the horse-hair shaving brushes now in trade channels, some of which are presumably infected, except a direct warning to the public not to buy or use such brushes. Dr. Cumming strongly urges the issue of such an appeal by State Health officials and its widest possible publicity, as the only way, pending additional legislation, to obviate their potential danger. The New York State Health Department has started a movement against the manufacture of shaving brushes out of horse-hair, in the effort to eradicate anthrax. A bill will probably be introduced at the next session of the Legislature to prohibit the manufacture and sale of horse-hair shaving brushes.

Hospitals Take Place of Jails in Housing "Drunks."—A veteran Salvation Army worker in Chicago is reported as saying that empty jails are no criterion of the good results of prohibition, and that there are more drunks now than before the Eighteenth Amendment went into effect, "but the reason is that all the drunks now adorn cots in the hospitals. The stuff they sell for booze sends men to hospitals and cemeteries."

Another Aftermath of Prohibition.—In the annual report of the superintendent of the Chicago Juvenile Protective Association statistics are given which seem to show an increase of 238 per cent. in cruelty to wives and children since the prohibition law went into effect, and a still more rapid increase during the last six months. The reaction of heavy drinkers has manifested itself in surliness and abuse of the family, according to the report.

New Home for Scientific Bodies.—A site for the new building in Washington which is to serve as a home for the National Academy of Sciences and the National Research Council has recently been obtained. It comprises the entire block bounded by B and C Streets and Twenty-first and Twenty-second Streets, Northwest, and it faces the Lincoln Memorial in Potomac Park. The Academy and Council have been enabled to secure this admirable site, costing about $200,000, through the generosity of the following friends and supporters: Thomas D. Jones, Harold F. McCormick, Julius Rosenwald and Charles H. Swift, Chicago; Charles F. Brush, George W. Crile, John L. Severance and Ambrose Swasey, Cleveland; Edward Dean Adams, Mrs. E. H. Harriman and the Commonwealth Fund, New York City; George Eastman and Adolph Lomb, Rochester; E. A. Deeds and Charles F. Kettering, Dayton; Henry Ford, Detroit; Arthur H. Fleming, Pasadena; A. W. Mellen, Pittsburgh; Pierre S. duPont, Wilmington; Raphael Pumpelly, Newport; Mr. and Mrs. H. E. Huntington, Los Angeles; Corning Glass Works, Corning, N. Y. Funds for the erection of the building have been provided by the Carnegie Corporation of New York.

Gift to Society for Prevention of Cruelty to Children.—A gift of $4,000,000 has been made by Mr. and Mrs. August Heckscher to the Society for Prevention of Cruelty to Children. The gift comprises a plot at Fifth Avenue and One Hundred and Fourth Street, with a new building endowment sufficient for maintenance. Within two years, it is estimated, the Society will have a complete new plant with a capacity for the care of more than double the present number of waifs and mistreated children that come under its protection.

Medical Interne Wanted.—The United States Civil Service Commission announces an open competitive examination for medical interne to fill, among others, vacancies in Saint Elizabeth's Hospital, Washington, D. C. Applications should be made before March 1, 1921, to the Civil Service Commission, Washington, D. C., or the local Secretary of the Civil Service Board.

Physician Wanted for Panama Canal Service.—An open competitive examination is announced by the United States Civil Service Commission to fill vacancies in the Panama Canal Service, at an entrance salary of $250 per month. Applications should be made to the Civil Service Commission, Washington, D. C., or the secretary of a local Civil Service Board.

Dr. Carleton Simon, alienist and criminologist, has been appointed Special Deputy Police Commissioner in charge of rounding up drug addicts in

New York City. Police Commissioner Richard E. Enright, in announcing the appointment, declared that the drug evil has assumed alarming proportions since the prohibition law went into effect. There are said to be 30,000 unregistered addicts in this city. Forty per cent. of habitual criminals here are addicts.

Dr. Henry Lyle Winter has removed his office to 24 East Forty-eighth Street.

Dr. Russell L. Cecil has removed his office to 33 East Sixty-first Street.

Dr. Nellis B. Foster of the Cornell Medical College will deliver the third Harvey Lecture at the New York Academy of Medicine, Saturday evening, Nov. 20. His subject will be "Uremia."

Obituary Notes.—DR. HENDERSON SUTER of Washington, D. C., died Nov. 6, as the result of a paralytic stroke suffered five years ago. He was graduated from the University of Pennsylvania School of Medicine in 1877.

DR. GOTTLIEB C. H. MEIER of New York City died Nov. 11, at the age of sixty-eight. He was graduated from New York University Medical College in 1880.

DR. WALTER GUY HUDSON, medical director of the E. I. Dupont Company and the General Motors Company, and an expert in the matter of safeguards in the use of explosives, died suddenly, Oct. 30, at his home in Yonkers, N. Y., at the age of fifty-two. During the World War Dr. Hudson served as chairman of the Sub-Committee on Industrial Diseases and Poisons, Advisory Board, Council of National Defense.

CAPTAIN R. D. WAINWRIGHT, U. S. M. C., retired, died recently at Norfolk, Va., at the age of seventy-one.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Oct. 22, 1920.

Annual Conference of the National Association for the Prevention and Cure of Tuberculosis.—The eighth annual conference of the British National Association for the Prevention and Cure of Tuberculosis took place at Liverpool on October 7, 8, and 9. Delegates to the number of about 1,000 were present from all parts of Great Britain. Sir Arthur Stanley presided on the first day and the meeting was largely concerned in discussing the comparative lack of success of sanatorium treatment in arresting the spread of pulmonary tuberculosis throughout the country. Many medical men who spoke stoutly defended the system and declared that not only had the best not been made of it, but that its greatest success could be achieved only in combination with other preventive measures. No doubt, however, that a main reason why the public and a goodly proportion of the members of the profession are somewhat prejudiced against sanatorium treatment is because when it was first introduced it was hailed by its too enthusiastic advocates as the one and sole means of successfully treating the tuberculous and of extirpating the disease. Of course, these far-reaching claims have not come to pass, and the consequence is that the sanatorium system is now condemned by many as a failure, whereas the truth is that in conjunction with other methods it should be and, when properly managed is a success. It supplies only a part of the treatment but a more or less essential part.

Dr. E. W. Hope, Medical Officer of Health for Liverpool, was down to read the first paper, but was unavoidably absent. In his absence Dr. Musson, the deputy medical officer, read the paper, which dealt with treatment and preventive measures and the results obtained. It was pointed out that the sanatorium was introduced with a flourish of trumpets, which resulted in inflated expectations among those who did not appreciate its precise functions, while the extravagant claims which its ardent supporters put forward gave the public the impression that admission to a sanatorium was equivalent to restoration to health, and exclusion to sentence of death. The disappointment engendered by failure to reach these expectations threatened at one time to retard the establishment of these institutions. It was a sad but justifiable criticism that the word "cure" was no longer used in connection with them. He drew attention to how much depended upon the type of case admitted and the duration of treatment, and pleaded for a recognition of the great value of educational methods of prevention in the treatment of tuberculosis.

Dr. Nathan Raw, M.P., declared that the fact that present results of treatment were unsatisfactory was due almost entirely to the patient being unable to devote sufficient time to his cure. The benefits of sanatorium treatment were largely nullified by the patient having to return to unsanitary home conditions and to attempt to earn a livelihood in the open labor market, only to find that he could not do a full day's work and finally breaking down. At best a consumptive had only 50 per cent. working capacity. Labor conditions must be arranged so that he could earn a modified wage. Soldiers and sailors to the number of 35,000 were demobilized with tuberculosis, and in the problem of taking care of them the Government must take full responsibility.

Dr. Halliday Sutherland contended that the results of sanatorium treatment were not better because patients were sent to sanatoriums at too late a stage, and the average residence was not long enough.

Dr. J. G. Adami read a paper in which he pointed out that it was more of an economic than a medical question. In the present state of our knowledge it was highly improbable that a drug could be obtained that would destroy the bacillus, and if there were such a drug he doubted whether it could be introduced into the body in sufficient concentration. Also it must be borne in mind with regard to the possibilities of a specific medicinal cure, that the bacillus has been known for two generations and that since the date of its discovery skilled men in various countries have endeavored to find a specific remedy and the result of their efforts have been partially successful only in regard to tuberculin treatment. The four essentials were early recognition, notification, isolation, and treatment. A combination of voluntary and official support was essential and would

be most economically brought about by the establishment of local tuberculosis dispensaries. Dr. Adami described the working at the Royal Institution, Montreal, of the class treatment introduced by Dr. Joseph Pratt of Boston and stated that in his opinion this method of treatment gave far better results than the sanatorium treatment and at a lower cost per patient. He advocated a modification of the system, together with the establishment of day camps and night camps for open-air treatment in the parks and gardens of cities and towns, as being the lines along which the best and most economical results could be obtained.

Sir Henry Gauvain thought that in fighting tuberculosis we had lacked a well-defined policy. Our army, he declared, was ill-trained, ill-equipped, unorganized, lacking in co-operation, had no staff officers, no authoritative leaders with full power to act. The teaching was ineffective. He spent more time as a student learning the anatomy of a frog than learning the nature of tuberculosis. He was taught, too, to operate on socalled surgical tuberculosis and to open up disease areas. There had been 110,000 primary notifications of non-pulmonary tuberculosis in the past five years and 59,000 deaths had occurred. At Alton, by other methods, out of 2,037 cases, they had lost only 52. In the first line of offence against tuberculosis was the general practitioner. He was not getting enough encouragement. Even more depressing was the position of the tuberculosis officer. There were half a dozen different officers all battened down in water-tight compartments, compelled to use certain materials, denied the use of others. Was it to be wondered at that there was a lack of co-operation? He urged the establishment of a diploma in tuberculosis. If the Government meant business they had better get trained men; ill-trained men were mere waste of money.

Milk as a Source of Infection.—On the last day of the meeting a discussion on milk as a source of infection and the preventive measures to be employed, took place. Sir Robert Philip, M.D., presided. The discussion was opened by Dr. O. W. Macfadden of the Ministry of Health, who pointed out that figures indicated the present exceedingly low consumption of milk in industrial districts, and the wastage in milking herds from tuberculosis. He suggested that public health authorities should combine with their direct endeavors to protect the community from dangers arising through milk, an active policy for increasing its consumption and to this end, encouraging the milk-producing industry in every way to attain its maximum commercial efficiency. Proposed new milk legislation should enable administration to be helpful in this direction. Professor J. M. Beattie of Liverpool claimed that proprietary milk preparations for the feeding of children were not practical substitutes for fresh milk, and that the sterilization or pasteurization of milk was not a guarantee against tubercle infection. Moreover, it was in its experimental stage and could not be said to be a success on a commercial scale. The rational method of procedure was to control milk at its source of supply and he suggested systematic inspection of dairy herds and examination of composite samples of milk from these herds, with special samples from animals suspected of tuberculosis, together with the isolation, on special isolation farms, of all suspicious animals. Sir Robert Jones of Liverpool said that one-half of the cripple cases among which he practically spent his life, were tuberculous in character. Further, two-thirds of the infection in these tubercle cases was bovine in character and one-third human. It was really a scandal that tuberculous cows could not be slaughtered, although those intended for butcher's meat could be. Dr. Dingwall Fordyce said that although it might seem ridiculous to say so, the medical profession was not as well educated as it should be in the elements of child nurture. It would be better for the nation that there should be small, healthy families than large ones, many members of which died. Dr. J. Rudd Leeson said that people had no business to drink milk. It was quite unnatural, as was shown by the fact that when a child's teeth came mother's milk ceased, and that applied to all mammalia. He regarded the drinking of milk as one of the curses of civilization. It may be interpolated here that Dr. Harry Campbell has long held the opinion advanced by Dr. Leeson. Dr. Campbell contends that when the teeth have come milk is not a natural food and not a good food for more than one reason. One strong reason that he brings against milk as a food for those who have their teeth is that it does not need mastication. Our teeth are where they are and our jaws are so constructed in order that we may chew hard food thoroughly, and hard food is our natural food because of the presence of our teeth and because in the evolution of man's diet we have become in our general physical make up largely carnivorous animals. If we do not use our teeth and jaws they degenerate and Dr. Campbell asserts that a cause of much of the dyspeptic trouble that is prevalent and of defective teeth which are so greatly in evidence, is the pappy mushy food that is eaten. If we wish to take milk when we are adults Dr. Campbell urges us to take it in the form of cheese, which is not only an exceedingly nutritious, tasty, and satisfying food but affords the exercise of the teeth and jaws which is necessary for their preservation and essential to good digestion by inciting by means of thorough mastication the salivary glands to perform their functions properly. While there is a good deal in what Dr. Campbell says, it does not alter the fact that an enormous quantity of cow's milk is consumed by young children and that it is in the best interests of the community that the food should be given in as pure a condition as possible. Professor Beattie stated without reserve what has been said before by many scientific medical men that neither sterilization nor pasteurization affords a sufficient guarantee against milk infection and that the only certain or fairly certain method of ensuring this result was to take measures to obtain milk pure at the sources of supply. But another speaker, Sir Robert Jones, made the statement equally true that tuberculous milk cows are extremely numerous, and that two-thirds of the cases of the tuberculous deformities with which he had to deal were bovine in character. Thus infection from this cause is

a menace. Again Professor Beattie declared that proprietary milk preparations for the feeding of infants were not practical substitutes for fresh milk. The situation then to be faced appears to be that cows' milk in existing circumstances in Great Britain is not a safe food for infants even if it be a nutritive food, which is doubted by some. Also that substitutes are not to be relied on. What then are the ways out of this serious dilemma. The most obvious and most effective mode would be to educate women to nurse their infants. But as things are this seems to be a Utopian idea, although every effort should be made to bring this about. The next best procedure would be to use every endeavor to ensure a pure milk supply, rigid inspection of cows and dairies, and uncompromising enforcement of the laws as regards proper transport, delivery in good condition and proper keeping in the shops in which it is retailed. All these desirable ends are impossible of accomplishment in a short time if ever, the cost would be too great and therefore reliance must still be largely placed on pasteurization and it should be seen to that this is effectively carried out and enforced in the strictest manner. There is little doubt that Great Britain could learn much and to her great advantage from America with respect to the control of the milk industry.

3. Lead in the Urine in Neuro-Circulatory Disturbances.—McDonald and McCusker, accepting Chapman's standard as the minimum amount of lead to cause symptoms and signs (from one-quarter to one-half a milligramme of lead per liter of urine, estimated by standard methods), report twelve cases. These cases represent nervous disorders of many types. Not one of them showed signs of lead poisoning, like the lead-line, anemia, or stippling. It was only by making a routine urinary examination for lead in doubtful cases that the lead element was discovered. The cases are reported, therefore, to stimulate corroboration or refutation of Chapman's standard, that four-tenths of a milligramme of lead per liter of urine is sufficient to cause symptoms; and to argue for the consideration of lead as the etiological factor, or one of the etiological factors, in obscure cases presenting neurological signs and symptoms.

6. The Use of the Thermometer in Mental Diseases.—E. D. Bond, recalling the fact that formerly the thermometer was considered of no value in mental diseases, and holding that there is not, even now, sufficient recognition of the importance of temperature records among the insane, gives the results of an examination of the temperature charts found in a series of seventy-one consecutive cases, singly and in groups. The patients were all women, admitted to the Department for Mental and Nervous Diseases of the Pennsylvania Hospital from January to July, 1916. Fevers, slight or severe, transitory or chronic, occurred in over 50 per cent. of the cases. The diagnoses are sufficiently varied, and show that fever has occurred in imbecility, epilepsy, arteriosclerotic dementia, general paralysis, dementia precox, and manic depressive psychoses. Of 19 cases of manic depressive insanity, 13 had fever and six did not. Of 19 cases of dementia precox eight had fever and 11 did not, this being the only disease in which normal temperatures were found more often than the reverse.

1. The Endocrines in Gynecology.—William P. Graves confines his discussion of the subject to the relationship of the endocrines to the specific neuroses of patients suffering from pelvic disease, and to the histogenesis and function of the internal secreting cells of the ovary. The more one studies the so-called nervousness of women, the more one is impressed with the possibility that the purely nervous mechanism of the body is of secondary importance. It is quite credible that the nerves are only the keys or instruments which are played upon by more dominant agents in the form of the endocrine glands. Whether women may be said to be peculiarly nervous or peculiarly endocrinous, the gynecologist undoubtedly accomplishes more accurate results if he estimates his nervous patients from an endocrinological rather than from a purely neurological viewpoint. Among other points with reference to the ovary as a gland of internal secretion the writer emphasized the following: Dysfunctions of the ovaries are usually attended with various neuroses. Some of these may be due to the direct disharmonious action of other endocrines, especially those that have an affinity for the autonomic nervous system. In evaluating these neuroses one must also take into account those neurotic habits which are the result of a sense of physical inferiority, and characterized as a continued endocrinous emotional state. From an organotherapeutic viewpoint the ovary must be regarded as primarily a homogenous gland, the essential secreting structure being the interstitial cells. Variations in secretions of different parts of the gland are probably differences of degree rather than of kind. A selective action of the secretion from different parts of the gland is not yet proved and if it exists is probably quantitative. All ovarian preparations exert a specific influence on hot flushes. In this respect the residue is the most intensive, but the difference in efficacy of the various preparations depends to some extent on the idiosyncrasy of the patient. In the treatment of menstrual irregularities ovarian extracts exhibit an undoubted specific action, but this action is inconstant. In temporary functional amenorrhea, delayed menses, dribbling before and after catamenia, and small clotting, ovarian therapy is fairly reliable, and is at least the best asset the gynecologist at present possesses for these symptoms. For the permanent amenorrheas, especially those associated with pluriglandular disturbances, ovarian therapy has little or no effect on restoring the menstrual function, but is of undoubted value in improving the patient's general health. In certain types of dysmenorrhea ovarian feeding is efficacious, occasionally brilliantly so, but is unreliable and often disappointing after giving early promise. In severe types of dysmenorrhea it is of comparatively little help. For menorrhagia and metrorhagia ovarian therapy is not indicated.

1. Abdominal Pain in Diseases of the Kidney and Ureter.—Arthur B. Cecil bases this paper on a critical review of 300 cases in which a complete urologic investigation has been carried out on the upper urinary tract. The study was undertaken for the purpose of determining the frequency of occurrence and distribution of abdominal pain in association with diseases of the kidney and ureter. The cases are classified under twelve main groups: stone in the kidney or ureter, renal tuberculosis, pyelonephritis, hydronephrosis, tumor of the kidney, polycystic kidney, nephroptosis, pyonephritis, chronic nehritis, congenital malformations of the kidney, cystitis, and a miscellaneous group comprising cases of essential hematuria, cases which were studied for differential diagnosis, various rare conditions, and those in which the findings were negative. The review of these cases shows that the most practical conclusions as to the distribution of abdominal pain in diseases of the kidney and ureter can be best arrived at by a study of those diseases which are most constantly characterized by pain, namely, stone and hydronephrosis. In the group of cases of stone in the kidney or ureter the distribution of the pain was purely abdominal in 28 per cent., and in 20 per cent. it was so misleading as to lead to abdominal operations. The figures from the tables on hydronephrosis are even more striking. Excluding the six cases of hydronephrosis which are associated with stone, it is noted that abdominal operations had been performed in 30 per cent. of the remaining cases, for the relief of pain which was subsequently demonstrated to have been of renal origin. The symptomatology of hydronephrosis is often obscure and misleading, and it is in this group of cases that the urine is so often practically normal. It is obviously impracticable to carry out urologic examinations as a routine. There are, however, certain well defined indications, and while abdominal pain is not one of them, it is by no means a contraindication, and becomes a definite indication when the urine shows abnormalities. In obscure cases of abdominal pain, pyelographic studies should be more frequently made. The writer concludes that emergency of operations in obscure abdominal pain does not depend on severity of the pain alone. Some of the severest types of abdominal pain have as their origin diseases of the kidney and ureter.

4. A Study of the Effect of Pulmonary Tuberculosis on Vital Capacity.—Wittich, Myers, and Jennings made observations on the vital capacity of 174 patients, 117 being cases of disease of the respiratory tract, 90 of whom were definitely classified as tuberculosis. They hold that the careful study of the vital capacity in its proper relationship to other body measurements will give important information in the diagnosis of pulmonary diseases, especially tuberculosis. It will aid in the accurate classification of the cases and in determining the progress of the disease and the influence of treatment. It is a simple and harmless method of determining the patient's actual physical fitness or limitations.

12. Types of Pneumococci in the Throats of One Hundred Normal Persons.—Jacob Meyer made this study of 100 normal individuals of varying ages, in whom no history of contact with an acute or recent case of lobar pneumonia could be obtained. Pneumococci were found in twenty-one instances. Types I and II were not found in any case. Type IIA was isolated once. Type III occurred in three instances, and Type IV in seventeen.

2. Extrapleural Thoracoplasty in the Treatment of Pulmonary Tuberculosis.—P. Bull gives his experience with extrapleural thoracoplasty in pulmonary tuberculosis in the following summary: 1. In unilateral, or mainly unilateral pulmonary tuberculosis, which is not cured by rational treatment (including pneumothorax), good results can be achieved by means of extrapleural thoracoplasty. 2. The operation should be performed only after conference with the physician treating the patient, who must have had an opportunity, by observation during a considerable period, of forming a thorough opinion of the prognosis in the case concerned. 3. Resection of the ribs should be carried out under local anesthesia through a paravertebral incision, so that the posterior part of the ribs from the eleventh, or, in any case, from the tenth to the first inclusive, can be removed. 4. If a cavity remains, it can be brought to collapse by means of intrathoracic transplantation of fat. 5. It is necessary that practising physicians should acquire knowledge of the indications and results of extrapleural thoracoplasty. One has now no right to withhold the chance of operation from suitable patients.

3. Sugar in the Blood.—Wallis and Gallagher present a microchemical method of estimation of the sugar content of the blood which they have tried and perfected. The method, which is based on that of Folin and Wu, provides an accurate, reliable, and rapid method of estimation of blood sugar. It enables an analysis of the blood to be made with very little inconvenience to the patient, as also the determination of the glucose tolerance, and yields results of importance both as regards diagnosis, prognosis, and treatment.

3. A Contribution on Blood Pressure in Graves' Disease.—Goodall and Rogers summarize their findings as follows: (*a*) In typical and uncomplicated cases of Graves' disease the systolic blood pressure is usually lower than normal, the diastolic pressure approximately normal, and the pulse pressure consequently low. (*b*) The systolic pressure passes through three phases: 1. *A Short stage of Primary Hypertension.*—This is associated with the onset of the disease, and due to vasoconstriction owing to suprarenal stimulation. 2. *A Prolonged Stage of Hypotension.*—This is due to peripheral dilatation caused by a depressor substance secreted by the thyroid, and is of variable duration, but usually lasts for years. 3. *A Stage of Secondary Hypertension.*—This comes on late in the disease, and is

associated with secondary changes in the cardiovascular system and reduced thyroid activity. (*c*) After operation on the thyroid the systolic blood pressure tends to rise. This rise is not infrequently associated with cardiac acceleration and an irregularity of the pulse due to auricular fibrillation, and possibly in extreme cases followed by ventricular fibrillation resulting in death. (*d*) A low systolic blood pressure in Graves' disease, other factors being equal, indicates from an operation point of view: (*i*) Little myocardial exhaustion. (*ii*) A small post-operative rise in blood pressure and consequently little liability to post-operative cardiac failure. (*iii*) Less hemorrhage. (*e*) Diurnal variations in blood pressure are considerable in Graves' disease, being relatively greater than in health.

10. Causation and Pathology of Atrophy of the Liver.—M. J. Stewart holds that atrophy of the liver is a toxic lesion in which the whole organ is more or less seriously injured. Certain portions are damaged so severely that the hepatic parenchyma undergoes more or less complete cytolytic disintegration while other parts survive, and the stage at which death takes place depends on the amount of tissue so surviving. Fatty changes are not a prominent feature in the areas which undergo necrosis, but are often present in the areas which survive. They are best seen in the so-called subacute cases—that is, after an interval of a few weeks or months. In case which recover, whether partially or completely, the persisting parenchymatous areas undergo regenerative hyperplasia, while often showing a certain amount of intervening portal cirrhosis and round-cell infiltration. The red areas of cytolysis and hemorrhage, on the other hand, become the seat of marked fibroblastic proliferation and round-cell infiltration, so that in course of time they become pale, firm, and sclerotic. They often show well marked proliferation of the bile canaliculi along the old portal tracts, and in chronic cases true functioning hepatic cells may be formed therefrom. The acute, subacute, and chronic atrophies of the liver so-called constitute a single morbid entity, and the different appearances seen post mortem are dependent on the stage of the disease at which death takes place, this in turn depending on the severity of the initial lesion. The lesions in the idiopathic atrophies and in those due to poisoning by trinitrotoluene and arsenobenzene are apparently identical. The lesions in phosphorus poisoning are of a different order, and are characterized primarily by extreme fatty degeneration, which may subsequently go on to widespread cytolysis.

Superfetation Diagnosticated by Radiography.—Schwaab reports the following case: A woman of 38 gave birth to twins one-half hour apart. The children were bioval and ordinarily the condition would have passed as ordinary twin gestation. The children however showed considerable dissimilarity, the first born weighing but 1900 gm. while the second weighed 2850 gm. The first resembled a premature although none of the characters of prematurity are specifically mentioned. The author had an inspiration to radiograph the children for the purpose of comparing the ossification. The state of the lower epiphysis of the femur should alone be sufficient because ossification occurs here during the last fortnight of intrauterine life and is a document that the child was born at term. The first born of premature suggestion was seen not to have undergone this consolidation, while in the other child this phenomenon was distinctly in evidence. This fact with the difference of almost 1000 gm. in the weight showed plainly that the children could not have been of the same age. Had the children been unioval this difference could have been explained by the fact that inequality of development is an expression of asymmetry such as sometimes occurs in such twins, but no such marked differences occur in these births. In another case of twin birth the difference in weight was 800 gm., but the radiograph showed that ossification of the lower epiphysis of the femur had taken place in both. In these twins but one placenta existed, while in the first example the children had separate placentas.

A Modified Borax Treatment of Epilepsy.—Marie, Crouzon, and Bouttier, starting with the well known fact that borax (boric acid) has a specific albeit mild power over epileptic seizures, have experimented with the borico-potassic tartrate. This double salt has been termed the "boric emetic," but this term is due to an error, for it possesses not a trace of such properties. It is also known as "soluble cream of tartar." In ordinary bromide medication the potassium salt has always been regarded as stronger than the other bromides, suggesting that the potassium component played some active rôle. Borax has had a limited use for many years. Tartaric acid does not seem to figure actively in the molecule but yields a double salt in which both boric acid and potassium are combined. In excessive doses the salt is a purgative. In testing a new remedy for epilepsy the reduction of the number of convulsive or minor seizures in a large number of epileptics is the criterion. The test is also made from the standpoint of the individual subject, since the treatment is apt to vary much with the personal equation. The only claim made by the authors appears to be that the new salt is more efficacious than any of the older boric preparations and hence may develop some usefulness in bromide-intolerant patients. Further, by acting as a synergist, it may enable one to reduce the usual dose of bromides. In serial attacks and cases of status the authors have succeeded in reducing the number of daily convulsions, while in other cases the number of monthly attacks was cut in two; but the failures offset such results and show that the drug will hardly supplant bromides in the treatment of epilepsy.

"Cream Cakes" and the Paratyphus B.—Lesne, Violle and Langle refer to the success of Lecoq in collecting 700 cases of alimentary intoxication (1900-1906), in which cream cakes figured as the cause. The motivation was originally given in succession as the use of copper vessels, vanillin, synthetic vanillin and ptomaines; until it was proved that the cause was a microorganism, and later it was shown that the paratyphus B was the chief or sole offender. A case is given in which the agency of this germ was proved beyond all question. The next subject to be considered was the cream which is responsible for so much morbidity. Samples were found to be excessively rich in germ life and study of smears and cultures brought out the fact that the chief or sole germ present belonged to the Salmonelloses and was very similar to but not quite identical with the paratyphus B. The chief difference lay in the absence of any reaction toward maltose. This difference may have been only a matter of adaptation. Cultures from the cream gave positive agglutination with paratyphoid serum but the action was not specific for the test was also positive with the Eberth bacillus. More significant, however, was the very short incubation of the fever of cream cake poisoning. The number of bacteria ingested at a time was enormous and a correspondingly large amount of endotoxin was thrown suddenly into the circulation. When exceptionally the incubation period was long the fever was typical of the paratyphus B. The cream from which the cakes are made seems fresh and sweet. It is prepared with white of egg and apparently the article is not the same as the American cream cake which is cooked. The cakes of the French appear to contain raw cream in some form but there is no mention of whipping or freezing, nor of special cakes like Charlotte de Russe or others in which raw cream is used.

Treatment of Myxedema.—Sainton briefly presents a subject which ordinarily should be summed up in a few words. He divides the subject matter into four sections: thyroid treatment, treatment by type, adjuvants and the minimal forms of hypothyroidism. As

grafting is not necessary to cure mankind and as an injection treatment is indicated only rarely, there is nothing to do but give the substance of the gland in daily dose of 5 to 50 cgms, according to age, tolerance, and degree of the disease. Treatment must be supervised as it is advisable to watch the cardiac and renal actions. The syndrome of hyperthyroidism should be avoided. There is a first period of adaptation, a second of full activity and a third of tentative breaking off. There are three major forms of myxedema—the spontaneous, the post-operative, and cretinism. The post-operative form yields very promptly while the cretin does well if he change his abode and especially if he goes to the seaside. The spontaneous form does better under treatment if the disease is of late appearance. In the very young child we may see intolerance readily develop and the benefit is apt not to be permanent. Adjuvants include antisyphilitics if the subject have inherited that disease and in general the use of tonics—lime, arsenic, phosphorus and iron, life in the open, sunbaths and a diet poor in meat and other foods which facilitate autotoxemia. The picture of mild hypothyroidism is taken from Hertoghe and Leopold-Lévy and very small doses only of thyroid are indicated—1 to 5 cgms daily.

Le Progrès Médical.

October 16, 1920, xlviii, 42.

Alkaptonuria.—Lereboullet presented a case of this rare affection in the course of a clinical lecture delivered at the Laennec Hospital. The urine in these cases is relatively clear on passage but rapidly turns dark brown on exposure to the air, and frankly black after the addition of an alkali. It is to be differentiated from true and false melanuria. Alkaptonuric urine will reduce Fehling's solution on boiling but the coloring matter is not a sugar although in some ways related to the sugars. As the name implies, it is known as alkaptone. The patient was a female who entered the hospital for fever and pulmonary and joint lesions. The urine resembled in color the strongest beer. Its color deepened on the addition of ammonia and it reduced Fehling's solution. The patient was taking sodium salicylate and this was suppressed but without effect on the color of the urine. At a subsequent period she reentered the hospital with congestion of the lungs and arthritis of the hip, and alkaptone was seen to be strongly present. This triad of symptoms of a relapsing tendency suggested some obscure disease process and such is known to exist—ochronosis—in which there should be deposit of pigment in some of the joints. But in this case it would be necessary to exclude two types of arthritis of the hip, the gonococcic and tuberculous, before assuming that the condition was due to alkaptone. The latter was not found either in the blood or stools. At the present time alkaptone, otherwise hydroquinone-acetic acid, is believed to be formed at the expense of tyrosine—in other words alkaptonuria is a form of aminoaciduria, which condition is regarded as due to hepatic insufficiency. In alkaptonuria an additional renal insufficiency is believed to exist. The resemblance of this metabolic affection to gout is seen to be considerable. To prevent and cure it one must abstain from giving drugs like salicylates which tend to compromise the kidneys.

Le Bulletin Médical.

October 9, 1920, xxxiv, 48.

Simulation and Alcoholism.—Jaguaribe and Sao Paulo, Brazil, and Regnault of Paris contribute an article on social pathology with this title. One of the authors, when an interne 30 years before, used to inscribe on the discharge sheet the diagnosis "pigrite" when he had reason to believe that the patient had been shamming sickness. The word is clearly a derivative of the Latin *pigritia*—laziness, indolence—which survives in the Italian *pigrizia*. Literally it would imply a man who shams illness because too lazy to work. During the elapsed years he has reached the conclusion that alcoholism is responsible for most of these cases. The chronic alcoholic is unequal to sustained effort or good work. A state of idleness due to chronic intoxication results. The workman who is paid on Saturday may drink until his money is spent, which may not be before Monday or later. After the indulgence comes the reaction. This type of man is the antithesis of the Petrarch type who works incessantly despite fatigue and when he at last stops work becomes ill from the sudden change of life, and recovers only when he resumes his occupation. Petrarch was of course a total abstainer. But the subject of *pigritia* may originally have been a hard worker of the Petrarch type who came in time to seek in alcohol an aid to his powers of work. Hence the word may be applied not so much to the alcoholism as to the condition which predisposes to it. In great crises which affect the entire community, such as earthquakes and pestilences, idleness is forced on the community, but even were work possible few could be found to perform it. In the recent war victor and vanquished presented the same symptoms. There was a tendency toward alcoholic abuse, which, however, could be indulged only to a limited extent, and to obtain money by crime intsead of hard work. The authors begin by the attempt to trace a connection between alcoholism and hospital grafting, but are led to a consideration of the state of mind which favors alcohol indulgence.

Gazette des Hôpitaux.

October 9, 1920, xciii, 86.

Diseases of the Endocrine Glands.—Lereboullet sums up the history and ensemble of this subject and reaches the following conclusions: These organs play a considerable rôle in pathology and by reason of excess, diminution or vitiation of their secretions cause many diseases. One gland only may be concerned at first, but the tendency is for several to be involved either simultaneously or in succession. We should not attribute the various syndromes merely to altered chemistry of the blood for there is another component which involves the autonomous nervous system. The benefit which accrues from the use of organ extracts in disease should not straightway be attributed to the making good of a deficiency, and the use of pluriglandular extracts is to be encouraged. Endocrine subjects can be improved by other forms of medication as seen in heredosyphilitics who present glandular syndromes and in which cases great benefits are obtained by opotherapy conjoined with antisyphilitic measures.

Ocular Symptoms of Tetanus.—Roques and Condat relate a fatal case of idiopathic tetanus in which a pupillary symptom was notably pronounced. The case was not an example of socalled cephalic tetanus in which the facial nerves are involved, but was of the usual type. The pupils alternately dilated and contracted with a wide amplitude (pupillary nystagmus), without rhythm and independently of the usual factors. The tremor did not cease during sleep or under the full influence of chloral. The dilatation could not be explained by exacerbations of pain alone but bore a notable connection with an approaching paroxysm for which it acted as a certain warning, the pain doubtless playing a causal rôle. It was not absolutely certain, however, that the affection was not due in part to the action of chloral.

First Medical College in China.—During the war between Japan and Russia in 1894 the Chinese Red Cross was formed to look after thousands of Chinese who were left homeless and destitute in the regions where fighting raged for many months. After the situation was relieved, a considerable sum of money remained, and upon decision of members of the General Council, ground was purchased near Shanghai and a large handsome building was erected as the Chinese Central Red Cross Hospital and Medical College for Chinese students. The hospital is completely equipped with the most modern apparatus and furnishings. Instruction in the college is in English only. The first year there were twenty registrants. Each received his degree as a competent practitioner. Graduates of this school, under the direction of Dr. S. M. Cox, and by use of methods discovered by his brother, Dr. Robert Cox, have done much to alleviate suffering from former severe epidemics. The Chinese are proud of the school and view the results of its work with much satisfaction.

Society Reports.

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Thirtieth Annual Meeting, Held in Atlantic City, September 14-17, 1920.

THE PRESIDENT, DR. WILLIAM MARTIN OF ATLANTIC CITY, IN THE CHAIR.

(*Continued from page* 839.)

Various Ways of Using the Current in Exophthalmic Goiter.—Dr. S. SOLIS COHEN of Philadelphia made this presentation, which he prefaced by saying that electrotherapeutics had suffered in the past by two opponents, one the ignorant and obstinate and those unwilling to learn what could be done by the proper use of electricity in medicine, and the other the uncritical enthusiasts and electrical practitioners who made claims that could not be substantiated. Both of these drawbacks had disappeared and the Association had done much in getting rid of them. In considering his subject Dr. Solis Cohen said there must be individualization of patients. One must be flexible in his formulas and modify his treatment in different patients and in each patient must change the treatment with the changing condition of the patient. What was beneficial in the early stage of the disease might be harmful in the later stages. He described two varieties of Graves' disease, the highly toxic cases with great activity of the thyroid gland, attended sometimes with fever, sometimes not, but always with great nervous excitement and high blood pressure; and, on the other hand, the case that might be sluggish in development, in which the nervous symptoms might be prolonged, but were not of the excitable, almost maniacal variety, and the blood pressure was as a rule below normal. In the treatment of the first variety rest was of prime importance and was sometimes incompatible with the employment of electrical methods. When the patient might be disturbed a little without deleterious effect, he had found autocondensation a most useful adjunct to treatment, but only an adjunct. When the excitement was not great and when the blood pressure was normal or subnormal, he had found the static spark machine coupled with the Leyden jars and the use of the resonator coil Oudin current in addition a valuable form of treatment. The spark from the resonator coil might be applied to one or the other side of the seventh cervical vertebra or at times over the gland on both sides when the enlargement was bilateral; on one side if the enlargement was unilateral. The strength of the current must be regulated by the subjective reaction. The patient should have not quite as much as he or she could stand. Another method was the application of the sinusoidal current over the seventh cervical vertebra somewhat after the method of Abrams of San Francisco. He had used galvanism, 10 milliamperes continuous application, three to five, eight to ten, fifteen to twenty minutes, according to the results desired. The faradic current might be taken alone or the sinusoidal current and in addition the interruptions of the armature. All of these methods had proven useful in different cases. He had also used ionization with iodine. This he had used not knowing whether it would do good or harm, for there was some foundation for the belief that the use of iodine internally in exophthalmic goiter was harmful. There were other electrical methods that might be useful, as for instance, diathermy. It was important to make a distinction between hyperthyroidism and Graves' disease, for they were by no means synonymous. Exophthalmic goiter was a surgical condition in only a minimum number of cases in which the tumor became a mechanical threat to life and comfort; if there was a great degree of thyroid intoxication which did not permit of the long waiting necessary to non-surgical treatment surgery was indicated or when the patient was unable to give up the necessary time for the application of non-surgical measures, then surgery might be indicated. Even after surgery had been done and skillfully done the disease was still present, disease of the autonomic nervous system and of the endocrine system.

Dr. ALBERT E. ROUSSELL of Philadelphia said his conclusions were much the same as those expressed by the speaker. In some cases which showed no increase in the size of the gland electrical treatments were useful. In conjunction with Dr. Pfahler they had been using the *x*-ray in suitable cases of hyperthyroid secretion with the object of causing destruction of the glandular tissue and thus decreasing the amount of secretion that entered the system. He was able to recall nine cases treated with more satisfaction in this way than by any other plan of treatment.

Dr. G. BETTON MASSEY of Philadelphia agreed with Dr. Roussell's statement with reference to the *x*-ray. Since he had been using deep penetration with the Coolidge tube, five milliamperes for five minutes, three times a week, he had obtained very definite results and some cures. For mild cases of hyperthyroidism he had for a number of years used iodine with the cathode on the gland and a gauze pad beneath the shoulders, with 10 to 15 milliamperes, for 15 to 20 minutes. With this procedure one had to watch the skin on account of the violent action of the iodine, and he advised the use of ointment afterwards.

Dr. WILLIAM BENHAM SNOW of New York said that exophthalmic goiter was due to defective metabolism, and unless we went back to the metabolism not only in our attempt to cure exophthalmic goiter but in curing other conditions, we were making a serious mistake, and there was nothing so effective in regulating the metabolism as the static wave current. It activated the cells of the body. As it was the function of the liver to destroy the toxins in the circulation, that was the first organ to treat. In the treatment of exophthalmic goiter he believed there was nothing as effective as the static wave current, using it over the back of the neck and over the thyroid gland. With this treatment the tachycardia had disappeared in less than a month. The *x*-ray was a valuable aid in advanced cases. It inhibited the thyroid secretion and the pulse came down gradually to approximately normal. When he undertook a case of exophthalmic goiter he usually asked for five months, as it generally took that length of time to properly treat a bad case. Remarkable results could be accomplished with electricity and the *x*-ray in cases of exophthalmic goiter. When this was said it had been thought that we were exaggerating, but as a matter of record we were not.

Myocardial Degenerations and Their Treatment.—Dr. ALBERT E. ROUSSELL of Philadelphia read this paper, in which he declared that contrary to general opinion diseases of the myocardium were more frequent than those of the endocardium in the proportion of 505 to 245. This did not include the myocardial changes secondary to valvular changes, which were in the majority of instances the actual cause of death. After discussing the protean etiology of myocardial degeneration and calling attention to the different forms of degeneration, he described a method by which one might recognize a faint cardiac murmur that might ordinarily be overlooked and which he believed was original with him. Ashner had noted that in most individuals pressure on the eyeball caused a slowing of the pulse rate up to ten beats to the minute through vagus inhibition, and Loeper and Morelot, in 1913, noted the abolition of this reflex in tabes. This cardiac inhibitory reflex might be considered as the bilateral group of cells in the medulla at the level of the nuclei of the origin of the vagi, and when the tonic action constantly exerted through this center was increased, cardiac inhibition resulted. For several months the writer had applied this method in the examination of all his heart cases and found that in the majority of instances this pressure exercised for about two minutes would not only accentuate existing organic murmurs, sometimes to a marked degree, but would also bring out a previously unsuspected murmur. On the other hand, functional murmurs would seem to diminish in intensity or entirely disappear. In the treatment of acute myocardial degenerations rest followed by gradual exercise was of main importance, with the exhibition of tonic doses of strychnine. The *x*-ray for lowering blood pressure produced only temporary results.

Dr. MARY L. ARNOLD SNOW stated that they had many cases of myocardial insufficiency in which the blood pressure lying and sitting had been reversed, the

patient presenting a higher blood pressure when lying than when sitting. In these cases they used mechanical vibration with the ball vibrator between the seventh cervical and first dorsal vertebræ one and one-half to three mintes, as decided by the condition of the patient. The relief afforded was relatively commensurate with the symptoms and pathology of the condition. Many post-operative cases and cases that had not only hypotension but reversal of the blood pressure had been brought to approximately a normal condition for the sitting and lying blood pressure by this treatment.

Capt. C. M. SAMPSON of New York called attention to the fact that diathermy was also an aid in the treatment of heart conditions. The pain in angina was due to anemia as well as to the distress of the heart muscle due to blocking. Diathermy would produce hyperemia in any part, and in the heart would overcome the symptoms due to anemia.

Dr. FREDERIC DE KRAFT of New York called attention to a report made in 1916 in which he spoke of the use of diathermy in the treatment of various heart conditions. If one started with a low current, 100 milliamperes, and a short spark gap, and then gradually increased the current, and watched the patient, for there must be perfect balance, on some cases of valvular heart conditions, one was able to get a good effect that was not obtained from medicines.

Phototherapy in Benign Diseases of the Skin.—Dr. HERBERT F. PITCHER of Haverhill, Mass., presented this paper, which was based upon data drawn from his practice and from cases referred to him by physicians who had tried the routine remedies without beneficial results. Chronic eczema, psoriasis, acne, and some other skin diseases were usually due to gastrointestinal disorders, delayed metabolism, and other deranged conditions causing autoinfection. D'Arsonvalization aided oxidation in the tissues, stimulated the sudoriferous and sweat glands; while the wave generator, sinusoidal and static currents improved metabolism and promoted elimination from the bowels and kidneys. In treating cutaneous manifestations, one must fully understand the physiological properties of the indicated modality, its quality and quantity, and acquire a technique as nearly perfect as possible. If it was the Roentgen-ray it must be remembered that it was a two-edged sword, capable of causing great injury as well as great benefit. It could be made to produce a sedative, a stimulating, or a destructive action, depending upon the milliamperage or the amount of current passing through the tube, the length of the parallel spark gap, the distance of the anode of the tube from the skin, and the time of exposure. In a way the ultraviolet or quartz light had the same qualities, except its destructive qualities were not so far-reaching even in intensive applications. Even where blistering occurred, the results were not much different from sunburn, for in a few days the blisters subsided, the skin peeled and a new epidermis formed as soft and pliable as formerly. In palmar eczema, where the skin was thickened and fissured, the static brush discharge was an excellent auxiliary to the *x*-ray. The writer discussed the method of applying the various modalities in varicose ulcers, pruritus, acne vulgaris, acne indurata, scar hypertrophy or keloid, hypertrophic scars, acne rosacea, lupus vulgaris, lupus erythematosis, herpes zoster, seborrhea of the scalp, alopecia areata and other skin affections. Much could be written, he said, on the beneficial results of the treatment by ultraviolet light in sycosis, furunculosis, and carbuncles; also for the Roentgen ray in ringworm, in favus, hyperidrosis, mycosis fungoides, multiple warts and leukemic tumors of the skin.

Importance of Technique in the Application of External Therapeutic Measures.—Dr. ALFRED T. LIVINGSTON of Jamestown, N. Y., presented this paper in which he described the proper method of administering ergot hypodermically which he had recounted in previous papers, emphasizing the importance of administering it slowly. After experimenting with many localities he had long ago settled upon the region over the left scapula or between the left scapula and the spine as the best for the purpose. The results would be more satisfactory if the patient was recumbent and lying on the right side, and remained recumbent for at least an hour after the administration of the dosage. He then spoke of dry-cupping and recalled that he had devised the vacuum cup many years ago. The more cups that were applied at the same time over the region of the congestion of inflammation the better. He had upon his own person applied nineteen of these cups at one time and was greatly soothed by the lowering of tension and the withdrawal of blood from the brain and spinal centers. He had found this to be the usual result when but a half dozen cups were used, placed either side of the upper portion of the spine, above, opposite, and below the seventh-cervical vertebra, the patient lying prone. Among the conditions helped by dry cups were headache, nervousness, mental confusion, insomnia, inflammations within the thorax, abdomen, and pelvis, including acute inflammation of the kidneys and even appendicitis. Dry-cups, galvanism, and ergot constituted a triumvirate of corrective power which were difficult to duplicate in any other three therapies. Conjunctivitis, blindness from optic atrophy and from wood alcohol by filling the orbits of the eyes with yellow clay paste, three-fourths of an inch thick on the closed lids, and a piece of tinfoil, tightly roll at one end on the negative rheophore tip and pressed on the clay to make contact. The current was then gradually turned on until the meter showed 10 milliamperes and this treatment was continued from one to two and one-half hours. Most remarkable results had been obtained by this treatment in apparently hopeless cases. In order to secure the many and varied results possible with galvanism too much emphasis could not be laid on the importance of using a *rational technique* and a *proper dosage* applied a *sufficient length of time*. Thus used, galvanism, the twin of vital force, would develop atrophied muscles (increase metabolism), awaken activity in an indolent organ, increase functional action in a gland, dissipate pain or nervousness, induce sleep, restore sight, hearing or other special sense in certain cases, and would remove fibroid hypertrophy and even pus through the natural channels of elimination.

The Rôle of Radium Needles in the Treatment of Malignant Disease.—Dr. WILLIAM L. CLARK of Philadelphia made this presentation, describing his early experiments in attempting to devise radium needles that would be suitable for the treatament of malignant disease. He was told that the secondary rays from the needles would produce necrosis and sloughing. This he determined to test out for himself. He found it quite true that one would get sloughs from the secondary rays in dry skin, but in malignant disease this did not occur unless the exposure was too prolonged. This was explained by the fact that in malignant disease the moisture around the needles absorbed the secondary rays. Unless the tissue was very much devitalized one could leave the needles in for twenty-four hours without causing sloughing. Radium capsules and plaques had a distinct field of utility, but the needles had made many things possible which were not possible without their use. The removal of a malignant growth from the mouth and of metastatic glands in the neck was pure folly because the migratory cells were not taken into account. The migratory cells in the ducts should be treated, not necessarily with the needle because they might be reached by the element properly filtered. The needle might be inserted right into the gland, which was absorbed, inhibited, retrogressed, and disappeared. Where the glands had broken down it might be possible to excise them and then insert a radium tube. They had had cases treated in this way in which they appeared to have inhibited malignant conditions. Therefore, he believed in all cases supposed to have metastases in the early slow stage, if they destroyed the localized lesion they might very seldom expect a cure, unless something was done to prevent the migration of the disease to the glands. Lantern slides were exhibited showing the use of radium needles in cancer of the stomach following gastroenterostomy, squamous epithelioma of the lip, a malignant growth of the mastoid region which, when treated with the radium needles, showed regression without great destruction. Results were also shown in angioma and glioma and other malignant conditions. Dr. Clark entered a protest against the taking of pathological specimens indiscriminately. In stomach and uterine cases they sometimes used the capsules and sometimes the needles. In cancer of the rectum they sometimes used electro-

thermy and sometimes the radium needles. He believed the radium needle had come to stay.

The Futility and Unfairness of Improper Technique in the Use of All Physical Measures.—Capt. C. M. SAMPSON, M. C., U. S. A., of Hoff General Hospital, Staten Island, N. Y., presented this paper, in which he expressed the opinion that the greatest obstacle to be overcome in placing physiotherapy on its rightful plane and giving it its proper place as a specialty distinct from either medicine or surgery, yet closely interwoven with both was the prejudice against its use existing in a good portion of the medical profession itself. The blame for this prejudice must be placed squarely where it belonged, upon the shoulders of unsuccessful users of physical remedies. The profession at large could hardly be censured for judging the different modalities by the results following their use, and these results in a very large percentage of cases were either nothing or worse. It did not require a great strain of the imagination to picture the intense prejudice that would have arisen against music at first had each purchaser of a musical instrument at once started upon a concert tour without waiting to acquire a technique and had each one given it up when the public failed to respond; yet this was a practical parallel to what had happened in the field of physiotherapy, the medical profession taking the place of the public in the simile. Before a surgeon's statistics could be accepted as reliable and as proving or disproving the value of certain procedures he must have acquired a good technique and this required a thorough understanding of every factor influencing the final results. To build a technique in physiotherapy demanded the same intimate knowledge of all these factors except the skill with the knife, and instead of this one had a wide assortment of physical remedies each acting in its own peculiar manner, some comparatively simple and some extremely complex. Why should not physiotherapy be judged as in surgery, not by the failures of the novice or of the irresponsible, but by the results of men of experience and ability? He believed that a recognition of the fairness of this was beginning to make itself felt and was one of the reasons for the fast diminishing prejudice now evident. Contrary to the not unusual idea that if a man had failed to make good somewhere else on the staff he was good material from which to make a director of a new physiotherapeutic department being established, it was a fact that the only man who would do was one who had proven himself a keen student and successful practitioner. There was no other specialty so absolutely demanding the broad influence of years of successful general practice as that of physiotherapy and one could safely predict failure for any man not intelligent or energetic enough to succeed in general practice. The technique of physiotherapy was a science which could be taught but the prescribing was an art which, like music, could only be acquired by the faithful. A most important point in technique was the proper blending of physical remedies. Rightly combined and sequenced, physical remedies would often amaze even an experienced user. They could not afford to lose from their clinic any one modality. The man who attempted to practise physiotherapy with only one remedy or class of remedies was sadly handicapping himself and his many inevitable failures would not only discourage him but were sure to react against the physical field as a whole. While it was unreasonable to ask a successful physiotherapist not to become enthusiastic, that enthusiasm should be kept within bounds, and should avoid destructive radicalism.

The High Potential Currents, Their Significance and the Indications for Their Use.—Dr. WILLIAM BENHAM SNOW presented this paper, in which he expressed the belief that static and high frequency currents with their numerous modifications in the hands of the physician who understood their physical characteristics and physiological effects were destined to play a very large rôle in the future of medical practice. The action of electricity as applied with high potential currents had nothing in common with the body currents, as some modern writers seemed to think, or with the currents of low potential, except in the qualities common to, and characteristic of all electric currents. By this he implied that the application of these currents as employed in therapeutics possessed qualities infinitely superior to the currents of low potential in their *influence upon metabolism* and in their *mechanical* and *thermic* effects as influencing the processes for which nature had not made adequate provision to overcome or control. The high potential static current possessed the property of diffusion by means of which it pervaded and passed through all the tissues of the body, back and forth, with every charge and discharge of the spark gap during the administration of the one-pole static wave current. During this passage of the current in and out of the body it influenced not only the cells but also produced energetic local responses where the current entered and escaped from the body causing successive energetic muscular contractions relative to the length of the spark gap and the size of the electrode. The static current and other modalities of high potential were especially capable of effecting the dispersion of local stasis and infiltration, rendering possible the prompt cure or relief of conditions not otherwise so effectually relieved. Clinical evidence had so fully established the validity of these statements that there was no likelihood of their being controverted, and no effort was longer made to do so except by those who were unfamiliar with the relative potentiality as compared with the currents of low voltage. The essayist gave a résumé of the variety of conditions favorably influenced by high frequency modalities employed and their relation as affecting the principles of administration. Details in connection with the use of the auto-condensation current in the treatment by auto-condensation were discussed and the importance of a proper technique emphasized. A uniform scale of dosage should be employed. A careful study of the relative effects of varying dosages either in point of time or milliamperage had caused a rise instead of a fall in blood pressure which was attributable to over-stimulation. It was the consensus of opinion of those familiar with the method that a dosage of 500 milliamperes administered on the auto-condensation couch with a cushion three inches in thickness for twelve minutes produced the maximum effect in lowering blood pressure. The best results were obtained when the current was administered from a directional source. The employment of the high potential currents by scientific methods evolved during the past two decades had opened to the medical profession and humanity prospects for the relief of suffering and the prolongation of life which prior to their introduction were impossible and which had been demonstrated as invaluable in the management of conditions inflammatory, infectious, and metabolic.

Diffusion of Foreign Ions into the Body by the Direct Current.—Dr. G. BETTON MASSEY of Philadelphia read this paper, in which he refuted recent statements denying the possibility of securing the specific action of medicines in a part of the body by diffusing its ions into it by the direct current. He stated that we were only now glimpsing at the true nature of ionization, and that we did not realize that drugs inserted into the body in watery solution during most of their stay in the body were in the ionic state, no matter how introduced, whether by the mouth, by hypodermic injection, or by ionization, the ionic state being the result of simple solution in water, and that these ions reached what might be called their "opposite poles," and gave up their charges *at any point* in the body when they met their affinities. This selective action between molecules, on which the physiological action of remedies of many kinds doubtless depended, was a simple electrochemical reaction between an atom or molecule deficient in electrons and its mate with an excess. Experiments in passing iodine through a potato and finding it as an active atom only at the anode should be interpreted to indicate that such was true of all drugs dissolved in the body as ions, with the understanding that the opposite pole was found within the body itself whenever the foreign body met its affinity. The practical value of medicinal ionization should be attacked only on clinical grounds, and preferably with adequate control experiments. Under such tests the method would be found valuable or valueless, the only explanation of the latter possibility being a failure to consider secondary factors in the work. The physical laws of which the main factors were portrayed by Leduc were as definite as the action of the planets.

Diathermy an Aid in Empyema.—Dr. A. B. HIRSH of New York read this paper, in which he considered certain cases of empyema in which even most persevering, faithful attention to approved surgical technique failed to induce closure of the diseased chest cavity, where the infective process refused to yield though repeated change was made in chemical agents intended to check the purulent secretion. It was under such circumstances, beginning in December last, that a number of cases at Hoff General Hospital were referred by the Surgical Section to the Section on Physiotherapy for possible betterment through application of one or more of its physical treatment measures. The conditions faced in such a case were those dependent upon an active infective process with abundant purulent process in a practically closed cavity the walls of which, through respiration, were in continual action. Two therapeutic indications were therefore presented, the first being to induce intense phagocytosis for removal of infective material, and, second, to markedly increase the arterial blood supply locally for improved nutrition of involved structures, having in mind the early closure of the pleural space by enforced growth of granulation tissue. The facts known in regard to diathermy suggested that this agent might be effective in these cases, hence its use was originated at Hoff General Hospital for this purpose. An illustrative case was cited in detail, as it served to bring out most of the difficulties presented by this class of cases. This patient had a history of empyema covering eighteen months, during which time he had undergone several rib resections. Finally an operation was performed, which was followed by diathermy, under which the case progressed favorably. It was given daily to the involved region. The one electrode, of 22 gauge Crooker metal, 5 inch by 8 inch, was placed directly over the inflamed area, including the incision scars and the discharging aperture. The other much larger electrode was held over the anterolateral surface of the left chest. The electrodes were to be shifted downward in the course of treatment so as to take in areas treated by the Dakin tubes. Starting at 300 milliamperes for 40 minutes, the current was in a few days increased to 650 milliamperes for 60 minutes; later, to 2000 milliamperes. A month later ultra violet light was added for its systemic effect. This had in view the excellent results obtained in treating chest cases, especially tuberculosis, with outdoor therapy. Each day the quartz lamp was applied at a distance of twenty-four inches for three minutes, to each body region, the chest, arms, legs, front, and back being rayed in succession. Areas where diathermy was applied were avoided so as not to interfere with its continuing action. Patients who had this general ultra violet treatment showed subjectively and objectively a better morale. At the end of six months roentgenograms showed a disappearance of the osteomyelitis, an almost complete correction of the chest deformity, and the wound had closed. Diathermy was now a recognized addition to the treatment of empyema in this institution. A study of the literature showed a growing tendency to use diathermy, in addition to other electrical modalities, in affections of the chest. It was generally indicated in the treatment of pleurisy, both of the serous and the fibrinous varieties.

Captain SAMPSON of New York said that following their success with diathermy in a few cases of empyema they were allowed to have a series of the worst cases, and it was on the results in this class of cases in which everything else had failed that the value of physiotherapy was to stand or fall. Two points he thought should be emphasized. The first was the influence of diathermy on infection. Applied to an area of infection it stimulated metabolism and the absorption of the toxins of dead bacteria and it strengthened the reparative processes. It brought more phagocytes to the field of action and gave the phagocytes more energy. Diathermy could be used at the same time that Dakin's solution was employed, as it did not change the composition of chemical solutions.

The Use of the Static Machine in Reconstruction Work in the United States Army.—Dr. C. L. BARBER of Lansing, Mich., presented this contribution, in which he stated that he had been a user of electricity in general and surgical practice for thirty-five years, and had seen many beneficial and happy results with its use as a remedial agent. In those cases in which he had not obtained the desired results he knew it was due to his not using the proper modality of treatment, at the right time and in the right place. It was his desire, he said, to stimulate the members of this society to a more thorough campaign to teach the value of physiotherapy, by reading papers and telling of their experiences to the members of their own county and State societies, and if possible to induce every medical college in the land to sustain a professorship and teach electrotherapy, and the value of static electricity as a remedial agent for the use of the general practitioner. In the reconstruction hospitals it was in acute strains, bruises, and contusions of the various joints and muscles, as well as those injuries that had become chronic in character, that the static machine proved a valuable adjunct to their armamentarium. A number of cases were cited, among them that of a private who had been in the hospital for two months with boils on the back of his neck. The effluevе from the deKraft pencil used once daily for four days effected a cure. Very many cases of neuritis, neuralgia, arthritis, synovitis, paresis, catarrhal deafness, myositis, locomotor ataxia, etc., came under the list of diseases that would yield to the subtle therapy of the static current.

Physiotherapy in the Treatment of Industrial Disabilities.—Dr. WILLIAM D. MCKEE of Haverhill, Mass., presented this paper, in which he spoke of the growing recognition of the importance of caring for the health of the industrial worker. The treatment of accidents and sickness, or, in other words, the disabilities of industrial life or occupations, now formed a large part of the work of physicians and surgeons in productive business communities. All plans for the proper care of those disabled by industrial pursuits must certainly include physical measures which had been found of such inestimable value in the reconstruction work of the army. Physiotherapy as embodied in the use of electricity, light, *x*-rays, heat, cold, water, massage and exercise could be used properly only as allied and interdependent agencies, any one of which alone had a very limited scope as a therapeutic value, so that to achieve the greatest measure of successful results our equipment must include several if not all of those means for producing the desired mechanical, chemical and heat or thermal effects. Sprains, fractures and contusions with their attendant congestion, swelling and local rise of temperature had been treated with most gratifying results with electrical and other physical agents. Arthritis and other bone and joint conditions were quickly relieved and permanently improved by those agents which produced heat and mechanical effects. The healing of wounds was greatly facilitated by the different healt producing factors which increased the peripheral circulation and promoted nutrition. The application of physical measures in the treatment of ailments and injuries pertaining to industry was relatively no different than that of other fields of existence, but a new point of view and an awakening on the part of the profession had been created toward the value of physical therapeutic treatment by reason of what had been accomplished by these means in the reconstruction of our disabled soldiers. Many of the big industries of the country now had completely equipped departments for physical therapeutic treatment and were employing physicians and assistants who were familiar with their use. The need and means of preventing disabilities and the necessity of employing physiotherapy or physical measures of treatment for those that did occur was a viewpoint which was being rapidly molded and adapted to the great service of restoring to active and useful lives those unfortunate victims whose ailments were classified under the term industrial disabilities.

Graduated Exercises in Cases of Functional Heart Disturbance.—Major B. W. CARR of Washington, D. C., contributed this paper, in which he said that an opportunity was rarely afforded to observe the effects of graded exercises on classes of young men with cardiac disturbances both organic and functional, under so favorable conditions as in the large army hospitals during the world war. A large part of the cardio-vascular patients coming under observation in the army hospitals were suffering from functional disturbances of

various kinds, dependent upon the nerve control of the heart action. A systematic course of graduated exercises of rhythmic type was found to possess special value with these cases. The writer was privileged to observe daily for some time the results of exercises of this type upon classes of cardio-vascular cases at Walter Reed General Hospital. The five grades of exercises used were as follows: (1) Passive and resistive exercise. (2) Active exercises, in lying and standing positions. (3) Active exercises with co-ordination. (4) To speed with co-ordination. (5) Walking and slow running, graded. In the lower grades special efforts were made to induce muscular relaxation and lower nervous tension. To this end the directions for the movements were given deliberately in a low tone of voice and the movements carried out slowly with rhythmic breathing. The effect was almost hypnotic and the spectators would note the somnolent effects of listening to the commands and watching the class. Rest periods with complete relaxation were frequent. The aide in charge kept close watch for the appearance of any untoward symptoms and in doubtful cases the pulse was taken at frequent intervals. After giving detailed instructions for these exercises and citing statistics to show the beneficial effect on the pulse rate, the decrease in pulse rate following exercise being noticeable in its constancy, he concluded that the value of graduated exercises in functional disturbances of the heart must be conceded, but in order to obtain good results the treatments should be carried out systematically and under competent supervision. Each case was to be considered individually and advanced in the grades only as the condition indicated. Exercises of the character of Grades I and II might be initiated early in many of these cases, and if judiciously selected, exercises would not be found inconsistent with the prescription "rest."

The Relation of Physiotherapy to Surgery.—Dr. FREDERICK J. COTTON of Boston presented this paper. He stated that for a dozen years or more he had depended on the physiotherapist's aid for results. The results of this work in the war had been very notable, but unfortunately, since the close of the war this improvement had not held in industrial cases. The real reason of this was that they were missing the main lesson—the value of team work. The physiotherapist who worked alone got no further than the surgeon who considered his operation the only thing worth while. This was true in the army and it was true now. The speaker reviewed a number of cases which had had physiotherapeutic handling in various hands, mostly in rather expert hands, and yet all save one, had lost time, often many months in an attempt to do what could not be done. The moral was that all surgical cases should be surgically reviewed; that surgeon and physiotherapist were mutually indispensable, each to the other; that the present tendency to erect clincs for physiotherapy was all wrong. They were going to have medical teams not for physiotherapeutic work only but for co-ordinating all means toward the recovery of this class of patients, teams that could utilize the service of the internist and the neurologist, as well as the surgeon and the physiotherapist.

Physiotherapy in the Treatment of Trauma.—Dr. MARY L. H. ARNOLD SNOW of New York presented this communication. She defined trauma in its broadest sense as "any injury to the body due to violence or a wound" and its causes might be mechanical, chemical or thermal, or bacteriological, infectious. It might be a fracture, neuritis, a bruise, a sprain, an inflamed joint, an atrophy, a over-strained heart, lacerations with subsequent development of scar tissue, myalgia, neuroses, including hysteria and traumatic tremor, a tennis elbow, a Charley horse, a dislocation with the resultant enlarged joint, an ulcer or gangrene, a burn with keloid and scar tissue, or an infection, but whatever its character, relief was the one desire of the afflicted individual. As an offset to the meagre offering of the pharmacopeia for the alleviation of the above conditions, physiotherapy was replete with modalities from which the surgeon might choose, selecting that whose action of which physically and physiologically was best suited to relieve the pathological condition presented.

Among these measures were radiant light and heat, dry heat, the static current including the resonator emeuve, the high potential modalities, including those of low frequency as well as those of high periodicity and high frequency, the *x*-ray, radium, the sinusoidal current, the galvanic and faradic currents, including ionization, hydrotherapy, paraffin baths, mechanical vibration and massage, exercise, and the ultra-violet light. The employment of these modalities on a rational basis called for a consideration of the relation of the physical properties of the agents to the physiological action upon the tissues. To illustrate, in the after treatment of a fracture, a sprain, or a mechanical injury, the indications to be met were the removal of edema, the relief of neuritis, muscular tension, and sensory disturbances, as well as the restoration to normal activity. For the edematous condition, radiant light and heat and mechanical vibration in the form of light vibratory friction over the muscles involved, and interrupted vibration over the joints, the static current and the brush discharge, diathermy or the vacuum tube connected to the static machine might be effectually used. The essayist described more in detail the method of applying these agencies and how they acted to produce the results desired. She then considered the effects of static electricity under the headings: (1) Circulatory effects; (2) relief of nervousness; (3) increase of diaphoresis; (4) increase of metabolic activity.

In that class of cases in which an injury was associated with infection, or in treating the after effects of an infectious process, a scar tissue formation, as for instance, the result of chemical action, as burns, the employment of radiant light and heat, or dry hot air, diathermy alone or as an auxiliary measure, and the *x*-ray or radium might be indicated. For septic infection the use of radiant light and heat or of dry heat or hot air was indicated. Radiant light and heat acted in acute and subacute infectious conditions, alone or as an auxiliary measure, by increasing phagocytosis, inhibiting germ activity, by stimulation, and by the elimination of toxic products. As a derivative measure it lessened stasis, lowered arterial tension, relieved an overworked heart and promoted the elimination of catabolic processes. In the use of diathermy, too much attention could not be placed upon time as a factor as it made for success or failure. The heating process should be gradual, the patient's tolerance being reached during the last fifteen minutes of the treatment, and treatments should consume less than three-quarters of an hour to an hour at a time. Their treatments, in all cases requiring diathermy, were given daily until improvement warranted a lessening of the number to every other day. When scar tissue was present the use of ionization, the *x*-ray, radium or ultra-violet light was indicated. The method of employing chlorine ionization was described and a number of cases illustrating the results in various conditions reviewed. In closing, Dr. Arnold-Snow stated that with its large equipment, its extensive range of action, its many modalities, and the marked benefits derived from their use when technically applied, physiotherapy was rich with possibilities for the treatment of trauma in the hands of any practitioner who would take the trouble to give the subject its due consideration.

Physiotherapy in the United States Navy.—Commander WILLIAM SEAMAN BAINBRIDGE delivered this address which was profusely illustrated by lantern slides. He stated that in 1916 he made recommendations urging that we might have in the United States Navy adequate physiotherapeutic departments in connection with one or more of the large base hospitals, but we were illy prepared for war, and illy prepared for peace, certainly in the navy. Last fall he had obtained permission to establish a fully equipped physiotherapy department in the Third Naval District. The details in connection with this work Commander Bainbridge described, and stated that since the department began its work they had given about forty thousand treatments and they were daily convincing the old line officers of its value and were winning their cooperation. The lantern slides demonstrated the methods employed and some of the very remarkable results obtained.

(To be concluded.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

West Virginia State Board of Health.

July 13, 1920.

(*Continued from page* 798)

MATERIA MEDICA AND THERAPEUTICS.

1. What is an alkaloid, a tincture, a fluid extract?
2. What drugs would you use hypodermically, to meet the following requirements: (1) To stimulate the heart's action; (2) To produce emesis; (3) To control hemorrhage?
3. What is the strength of normal salt solution? How would you prepare same from common table salt? Give indications for its use, and modes of administration.
4. How is nitrate of amyl used, and for what purpose?
5. Give principal alkaloid of belladonna, indication for its use, also dose.
6. What is the physiological antagonism between belladonna and morphine?
7. Give the preparations of bismuth, how administered, and indications for use.
8. Give the preparation and doses of the mineral acids and their therapeutic effects.
9. State source of quinine; for what is it a specific?
10. Give complete treatment for a case of dysentery.
11. Write a prescription for a general tonic, same to contain tincture of nux vomica and a preparation of arsenic.
12. Write a prescription for a syphilitic adult, same to contain potassium iodide and corrosive sublimate in solution.

PRACTICE AND PEDIATRICS.

1. Give symptoms and treatment of scarlet fever.
2. Give etiology, symptoms, and treatment of erysipelas.
3. Give symptoms and treatment of influenza.
4. Give symptoms and treatment of acute nephritis.
5. Give symptoms, treatment, and cause of urticaria.
6. Differentiate between gastric and duodenal ulcer.
7. What is neuritis; symptoms and treatment?
8. Differentiate between bronchial and lobar pneumonia, and give treatment of lobar.
9. Give method of preparing milk for a baby two months old.
10. What is marasmus, and its treatment?
11. Give symptoms, incubation period, and treatment of measles.
12. Mention four complications of gonorrhea, and what is the State law relative to venereal diseases?

OBSTETRICS AND GYNECOLOGY.

1. What are the synonyms for obstetrics?
2. What are the immediate and remote dangers of abortion?
3. How can a foot be distinguished from a hand, or a knee from an elbow?
4. When should the forceps be applied in a labor delayed by weak uterine contractions?
5. Is the induction of premature labor indicated when children of previous pregnancies have been still-born from excessive development? Give reasons for your opinion.
6. What do you mean by the mechanical phenomena of labor?
7. What is included in the term external genitals?
8. What are contained between the folds of the broad ligament on either side?
9. What are the dangers in the use of the uterine sound?
10. What are the varieties of perineal laceration?
11. What are the chief causes of enlargement of an ovary?
12. Define metritis and endometritis; give etiology of each.

ANSWERS.

MATERIA MEDICA AND THERAPEUTICS.

1. An *alkaloid* is an organic substance, basic in character, containing carbon, hydrogen, nitrogen, and generally oxygen; it has a very complex constitution; it acts with acids to form salts in the same way that ammonia does.

A *Tincture* is an alcoholic solution of a non-volatile substance.

A *Fluidextract* is a solution of a vegetable drug, of such strength that 1 cc. of the fluidextract represents 1 gram of the drug.

2. For hypodermic use. A *cardiac stimulant*, atropine sulphate. An *emetic*, apomorphine hydrochloride. *To control hemorrhage*, adrenalin.

3. Normal salt solution is of the strength of 0.7 of 1 per cent. It may be prepared from common table salt by placing a teaspoonful of salt in a quart of warm boiled water. It is *indicated* in shock or hemorrhage, as an irrigating fluid, and for intravenous infusion. *Method:* An aspirator needle is sterilized by boiling, and is then inserted into the loose connective tissue of the buttock, back, abdomen, or axilla. The needle is connected with a reservoir by means of a rubber tube, and the reservoir held several feet above the point of insertion of the needle, so that the fluid is slowly forced into the tissues, forming a swelling which slowly subsides as the fluid is absorbed. If more than a pint is injected the needle should be introduced in another situation.

4. *Nitrite of amyl* is used by inhalation; in cases of angina pectoris and cardiac dyspnea.

5. The principal alkaloid of belladonna is atropine. *Therapeutic indications:* For the relief of pain, to dilate the pupil, to check secretions, for diarrhea, for asthma, for shock and collapse, for colic of all kinds, for delirium, for epilepsy, chorea and migraine, for paralysis, for cough, in constipation, in chorea, spermatorrhea, or cystitis. Dose, 1/150 of a grain.

6. The physiological antagonism between *Belladonna* and *Morphine* is as follows: *Belladonna* (1) acts as an excitant and stimulant of the cerebrum; (2) produces dilatation of the pupil; (3) quickens the pulse; (4) first stimulates and then depresses the respiratory center; (5) decreases all the secretions, except urine.

Morphine (1) acts as a sedative on the cerebrum; (2) contracts the pupil; (3) slows the pulse; (4) does not at first depress respiration, but in overdose it paralyzes the respiratory center; (5) checks all the secretions except perspiration.

7. The official preparations of bismuth are: The citrate, bismuth and ammonium citrate, the subcarbonate, the subgallate, the subnitrate, and the subsalicylate.

Therapeutic uses of bismuth: "Bismuth salts, as dusting powders and in ointments, are used for excoriated surfaces, wounds, etc., and in the treatment of skin diseases. The subnitrate, snuffed into the nostrils, is employed in coryza and simple ozena and as a topical application in aphthous or nursing sore mouth, mercurial ptyalism, chronic conjunctivitis, and granular lids, and ulcers of the rectum. Internally bismuth salts are useful in gastralgia, vomiting, gastritis, and diarrhea, and as intestinal antiseptics."—(Wilcox's *Materia Medica.*)

8. Mineral acids. *Preparations and doses.*—Aromatic sulphuric acid, dose 15 minims; diluted sulphuric acid, dose 30 minims; diluted nitric acid, dose 30 minims; nitrohyrochloric acid, dose 3 minims; diluted nitrohydrochloric acid, dose 15 minims; diluted hydrochloric acid, dose 15 minims. *Therapeutic effects.*—Any well diluted acid will check slight hemorrhages; sulphuric acid has been used locally to check the night sweats of phthisis; dilute nitric and sulphuric acids have been used in diarrhea; dilute hydrochloric acid is given to remedy deficiency of acidity of gastric juice; dilute nitrohydrochloric acid is used in disordered conditions of the liver.

9. *Quinine* is derived from cinchona; it is a specific for malaria.

10. *Treatment of bacillary dysentery.*—"In *acute* cases the patient must be confined to bed, and the food must be fluid (milk, chicken tea, barley water, etc.). Pain and tenesmus may be met by morphia, or small

laudanum enemata. The ipecac treatment is much favored in the tropics. The stomach being kept empty for three hours, m. xx of laudanum are given, and in about twenty minutes gr. xx-xxx of ipecac, followed by *absolute rest on the back.* If rejected, the dose is repeated, and the same dose is given every eight hours or so for two or three days. Alternatively Sodii Sulph. 3i may be given every two hours till a feculent motion is produced, and then so as to produce two or three motions daily. When mucus and blood have gone, bismuth and opium are given till the motions are solid. Calomel, gr. ¼ to ½, every hour, or minute doses of perchloride may also be given in the acute stage. Irrigation is contra-indicated by the pain and irritability of the bowel. *Chronic* cases must be treated at first by rest in bed and careful dieting, combined with irrigation. Two to four pints of a warm (100° F.) solution of nitrate of silver (grm. 1.0 to 3.0 to the liter) are allowed to flow slowly through a long tube into the bowel, the patient lying on his back with the buttocks raised on a pillow. Large doses of bismuth are also useful. *Serumtherapy:* A polyvalent serum has been prepared by Shiga, and used by him with good results. Other observers are not so enthusiastic. A vaccine has been beneficially employed in chronic cases."—(Wheeler and Jack's *Handbook of Medicine.*)

Treatment of amebic dysentery.—"Rest in bed and light or liquid diet are required, according to the severity of the case. Symptoms may be relieved as in bacillary dysentery, but internal remedies (ipecacuan, antiseptics, etc.) are of little use. Irrigation of the bowel is the most important measure, and Osler strongly advocates warm solution of quinine in strengths increasing from 1 in 5,000 to 1 in 1,000. One to two liters should be used twice daily. Nitrate of silver may also be used. The treatment of hepatic abscess is surgical."—(Wheeler and Jack's *Handbook of Medicine.*)

11. ℞

Ferri et ammonii citratis ʒj
Tincturæ nucis vomicæ
Liquoris potassii arsenitis āā 3ij
Tincturæ calumbæ ʒj
Syrupi limonis ʒij
Aquæ q.s. ad ʒviij

Misce et signa: One teaspoonful, three time a day, after meals.

12. ℞

Potassii iodidi ʒiv
Hydrargyri bichloridi gr. ij
Syrupi sarsaparillæ compositi ʒiv

Misce et signa: One teaspoonful after meals.

PRACTICE AND PEDIATRICS.

1. *Symptoms of scarlet fever.*—The principal features of the onset are vomiting, rheumatic pains, soreness of throat, high fever, and headache. In infants, convulsions are not uncommon. Soon the throat becomes very sore, the neck feels stiff, and the glands at the angle of the jaw are swollen. On the first or second day the rash comes out, first on the chest, then rapidly spreads over the face, body, and extremities. Its appearance may be delayed for a day or two. As the fever progresses, the throat symptoms become more severe; the tonsils approach the middle line, and yellowish points appear. These may coalesce and form a "patch" resembling that of diphtheria. The *tongue* is at first covered with thick white fur, with papillæ projecting—*i.e.* the white "strawberry" tongue; later, the fur peels off, leaving the typical red "strawberry" or "raspberry" appearance. There may be ordinary febrile albuminuria, even when there is no nephritis. The diazo-reaction may be present.

Treatment of scarlet fever.—The treatment is that of infectious fevers in general, and in addition: "1. *Serum treatment.*—Serum from convalescents, injected in doses up to 20 c.c., has sometimes proved successful. Good results have also been obtained with polyvalent antistreptococcic sera (*i.e.* sera prepared from several different strains of cocci). 2. The danger of spreading the disease is greatest during the desquamative period. Isolation must therefore be kept up for at least six weeks from the onset, or till all desquamation and discharges (nasal, aural, etc.) have ceased. 3. A minimum amount of nitrogenous food, to avoid irritation of the kidneys. This caution does not affect milk, which may be freely used. 4. Daily toilet, tepid sponging, or tepid baths. 5. Inunction of oily antiseptic preparations into the skin, to prevent dissemination of the desquamating scales. 6. Examine the urine daily for signs of nephritis. 7. The condition of the ears must be carefully watched."—(Wheeler and Jack's *Handbook of Medicine.*)

2. ERYSIPELAS. *"Etiology: Predisposing causes.*—(1) A wound or abrasion; (2) constitutional debility; (3) bad hygiene. *Exciting causes: Streptococcus erysipelatis,* which is indistinguishable from the *Streptococcus pyogenes.*

Symptoms: Malaise with rigor and headache. Rash appears within twenty-four hours; it appears first around the wound, which breaks open; it is of a vivid red color, which fades on pressure. Pain and swelling are not much marked. The eyelids and scrotum when affected become very edematous. Vesicles and bullæ form superficially, and a fine desquamation occurs, with some staining of the skin as the rash fades away. The margin is well marked, rather gyrate, slightly swollen, rapidly advancing. Sloughing of the skin rarely occurs, and then usually in cases of scrotal affection. Lymphatic glands in the neighborhood are enlarged and tender. Extension may occur by the lymphatics or veins to the deep structures, or pyemia may be set up. Constitutionally, the patient is very ill, with high temperature—102° to 104° F. Delirium is frequent, especially when the scalp is affected. Vomiting is common. —Grove's *Synopsis of Surgery.*)

Treatment: Prophylaxis.—Secure the asepsis of all wounds. All cases should be isolated to prevent the infection of others. *Local.*—In most cases all that is necessary is to apply lead, or lead and opium lotion. This has no curative action, but it relieves the stiffness and burning. Other applications, such as ichthyol, are used, but do not hasten the termination of the process. A form of treatment which aims at getting ready a supply of phagocytes at a distance of 2 inches from the spreading margin is the most promising. The skin is irritated by free scarification, and the tissues then become infiltrated with leucocytes, which are ready to attack the cocci when they spread in this region. The part is kept covered with carbolic fomentations (1 in 40). *General.*—Good food and stimulants. The bowels should be kept acting by magnesium sulphate, and 2 to 4 grains of quinine with 15 minims of the tincture of perchloride of iron are generally given every four hours. Antistreptococcic serum sometimes is very useful, either injected or given by the rectum. The treatment of cellulocutaneous erysipelas is that of cellulitis." —*Aids to Surgery.*)

3. INFLUENZA. *Symptoms.*—"The onset is sudden. There are severe frontal headache and backache, pains in the bones, and marked weakness. The temperature rises smartly to 102° F. or even 104°. Coryza and catarrh of the upper air passages are present, and the larynx or pharynx is often involved. In mild cases convalescence sets in in a few days, but a feeling of prostration persists for a considerable time. In severer cases, after the first few days, the disease assumes one of three types: (1) *Respiratory type,* in which bronchitis, bronchopneumonia, or croupous pneumonia develops. (2) *Gastrointestinal type.*—Epigastric pain, vomiting, diarrhea, and anorexia, associated sometimes with jaundice and enlargement of the spleen, are the commonest symptoms. (3) *Nervous type.*—The initial pains are more severe, and after defervescence the heart becomes slow or irregular and there is sometimes anginoid pain. Great depression and insomnia follow. In grave cases there may be coma or delirium.

Treatment.—"Rest in bed should be insisted on even in the mild cases, and continued for a day or two after the temperature has become normal, in order to avoid the risk of relapses or complications. The sputum and nasal secretion must be disinfected. Great care must be taken during convalescence, especially in the elderly. The pains of the first stage are best relieved by salicylate of soda, or where headache is severe by phenacetin (acetphenetidin). Quinine is also useful at this stage. Diarrhea may be checked by warmth to the abdomen and by fluid foods; bismuth and sedatives are of little use. For insomnia, bromides may be given, particularly the bromide of ammonium. In convales-

cence, tonics, and especially strychnine, are of importance. Complications must be treated as they arise."—(Wheeler and Jack's *Handbook of Medicine.*)

4. ACUTE NEPHRITIS. *Symptoms.*—"At first chilliness, pain in the back, vomiting, and pain over the brows; the temperature is raised (but may never be high); and the characteristic edema rapidly appears, at first in the eyelids, cheeks, and ankles, and later it may become general. The pulse is usually quick and of high tension from the beginning. The urine is voided frequently, but is scanty in quantity, and indeed may be suppressed for a time. It is dark from the presence of blood, exhibits the well-known smoky hue, and generally gives a copious deposit of urates, blood discs, granular debris, epithelial and hyaline casts, and blood casts, and a large amount of albumin. Though the urine is of high specific gravity, the total amount of urea passed daily is much decreased. Dropsy may be very slight, or may go on to anasarca; there may be dangerous dropsy of the serous sacs, edema of the base of the lung or of the glottis. Anemia is marked. The bowels become constipated, the tongue dry, and there is great thirst. Hypertrophy of the heart is seldom marked in acute cases, although acute dilatation of the heart may occur. If improvement does not quickly take place, grave dangers arise from the development of uremia; and intense headache, convulsions, and coma usher in a fatal termination. Most cases, however, with care, recover; others pass into the subacute stage or "large white kidney."

Treatment.—"Absolute rest in bed, the patient being laid between blankets, dry cupping followed by hot poultices over the loins, a free saline purge, diluents, such as bitartrate of potassium ʒi, syrup of lemon ʒiss, water ʒxx, and a non-nitrogenous diet, form the routine treatment. The diet should, if possible, be of milk only. Remember that nitrogenous extractives are highly irritating to an inflamed kidney, hence the necessity of diminishing the quantity of proteids taken and of withholding such preparations as beef tea. Acetate of potash and nitrous ether with hyoscyamus form a useful mixture, as we have at once a diuretic, a dilator of the peripheral arterioles, and a sedative to the urinary tract. But if there is excessive renal congestion causing marked diminution or suppression of urine, diuretics should not be given till the congestion is relieved by cupping, hot air baths, or leeching, and it may even be advisable to allow nothing but sips of water for the first few days. During the convalescence the anemia should be treated by iron."—(Wheeler and Jack's *Handbook of Medicine.*)

5. URTICARIA. *Symptoms.*—"The eruption appears suddenly, manifesting itself as firm, circumscribed, whitish or pinkish elevations with a reddish areola. The wheals last from a few minutes to several hours, disappear, and are succeeded by others. They are asymmetric, though usually bilateral, pea-sized or bean-sized, and irregular in shape, often, however, being linear. They may involve any portion of the cutaneous surface, or even the mucous membranes. The itching in urticaria is intense, the relief produced by scratching being purchased at the cost of the excitation of new lesions. The skin is markedly sensitive to all sorts of irritation, and responds by the production of wheals. In some urticarial subjects a word may be inscribed upon the skin with a pointed instrument, and in a few minutes the letters will stand out in wheals as if embossed."

Treatment.—"In severe acute cases seen early an emetic should be administered to get rid of the offending substance. Later, magnesium sulphate is to be employed until free catharsis is produced. In subacute cases salol or phenacetin, in 5 to 10-grain doses after meals, may be used with good results. In chronic cases most earnest efforts should be directed toward the discovery of the cause. The patient's dietary must be the subject of the most careful study. Every detail of occupation, of mode of living, and of habits must be scrutinized. The most careful examination, however, will sometimes fail to disclose any discoverable cause. Most cases will be found to be due to gastrointestinal disturbances. In such the most simple diet should be prescribed. In obstinate cases one will do well to restrict the patient for a few weeks to a milk diet. In obscure cases some of the following remedies may be tried: atropin by mouth or hypodermically, antipyrin or phenacetin, quinine in full doses, sulphurous acid in dram doses, long-continued course of arsenic in small doses, bromid of potassium, pilocarpin, etc. Local treatment is necessary to give relief from the harassing itching. The best antipruritic lotions are: Phenol, 1 to 3 drams to the pint; menthol, 5 to 15 grains to the ounce; liquor carbonis detergens, 2 to 3 drams to 8 ounces of water; saturated solution of benzoic acid; alkaline baths (¼ of a pound of washing soda to 20 gallons of water), etc."

Cause: "The great majority of cases of acute urticaria are produced through the alimentary tract. Substances taken into the stomach may cause urticaria, either by a mechanic irritation of the stomach or bowel or by producing a toxemia. Intestinal parasites and undigested aliment act by mechanic irritation. The substances capable of producing toxemia are almost numberless. They may be primarily toxic, or may only develop their toxicity through putrefactive changes while in the bowel. Again, a large number of substances, both foods and drugs, perfectly innocuous to the ordinary individual, act, on account of idiosyncrasy, as poisons to others. The following articles of food are particularly apt to produce hives: lobsters, crabs, mussels, cheese, sausage, pork, nuts, strawberries, etc. The following drugs are prone to produce urticarial eruptions: quinine, copaiba, cubebs, salicylic acid, morphine, turpentine, chloral, etc—(From Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

6. *Gastric ulcer* is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five: after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

In *duodenal ulcer* the pain is apt to be more to the right, and to occur at an interval of two or three hours after meals; the hemorrhages will be intestinal, and the blood will be passed by way of the bowels, and not vomited. In many cases the symptoms are identical with those of gastric ulcer.

In *ulcer of the duodenum* the symptoms are very similar to those found in ulcer of the stomach; but in the former condition there is less tendency to vomit, the pain does not come on till some time after food has been swallowed (and has had time to pass the pylorus), and blood in the stools is more common. All of these points are due to physiological and anatomical reasons based on the relative position of the stomach and duodenum. A special sign of duodenal ulceration is the so-called "hunger pain" which occurs at the end of digestion, when the unmixed acid of the gastric juice is passing into the duodenum. This pain is relieved by taking food, for when this occurs the pylorus closes, and the gastric juice is for the time retained in the stomach to be mixed with the food, while the alkaline duodenal and pancreatic secretions are stimulated.

7. *Neuritis* is an inflammation of the nerve-trunks, characterized by pain, impaired sensation, motor paralysis, and atrophy.

Symptoms: "The onset may be accompanied with febrile reaction. The most decided symptom is pain with tenderness along the course of the nerve-trunk and its peripheral distribution, of a burning, tingling, tearing, intense character, increased by pressure or motion. If the affected nerve be a mixed one—sensory and motor—spasmodic contractions and muscular cramps occur, followed by impaired motion, terminating in paresis of the muscles innervated by the affected trunk. The sense of touch and of pain are markedly impaired, while the temperature and muscular sense are but slightly disturbed.

If the inflammation proceed to destruction of the nerve-trunk, wasting and degeneration of the muscular tissue ensue. Various trophic changes also occur, such as cutaneous eruptions and clubbing of the nails. The electro-contractility is impaired or lost.

Treatment: "The affected part should be placed at rest. Repeated blistering along the course of the nerve, preferably with the Paquelin cautery, together with the administration of full doses of potassium iodide is usually successful in relieving the condition. Sedative lotions will also serve to lessen the pain. Sodium salicy-

late, phenacetin, and antifebrin may be of value at times, but in severe cases morphine hypodermically, is necessary. In syphilitic cases, the iodides are indicated, and in those due to exposure to cold and wet and rheumatism, the salicylates and alkalies are of great value. In all cases quinine sulphate, gr. ii to v, every four hours, should be employed from the onset. As the acute symptoms subside, galvanism or a feeble, slowly interrupted faradic current should be used to restore the functional activity of the affected nerve and the muscles to which it is distributed. Potassium iodide and strychnine during this period are also of value."—(Hughes' *Practice of Medicine.*)

LOBAR PNEUMONIA	BRONCHIAL PNEUMONIA
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

The *treatment of lobar pneumonia* "depends entirely on the type of case, and the condition of the patient. Routine treatment is the worst of all treatments. Answer the following questions before prescribing: Is the patient full-blooded, and is there a full bounding pulse? Is the pulse feeble, irregular, or intermittent?

"In the first case, in a young and previously healthy adult, if there be cyanosis, or signs of dilatation of the right heart, blood-letting to the extent of a few ounces may perhaps relieve the strain, but more generally treatment should be directed to maintaining the strength from the outset.

"In the latter case we can hope for nothing from a depressing treatment, so stimulants must be resorted to, such as alcohol, ammonium carbonate, egg and brandy mixture, quinine, ether, etc. The giving or withholding of alcohol depends upon its effect upon the pulse; should the pulse rate fall and the tongue become moist it may be continued. In asthenic cases, strychnine hypodermically is necessary from the outset, and normal saline may be given by the rectum or by the skin. Oxygen inhalations are used where there is cyanosis, but it is doubtful whether they have saved many lives. When there is evidence of failure of the heart (weakness of the second pulmonary sound, etc.) digitalis should be resorted to. Many prescribe it from the outset.

"The diet should consist of milk, beef-tea or broths, white of egg, and so on. The patient should be as little moved as possible, and the bed-pan must be used. As in other fevers, an airy room and good nursing are essential.

"Remember that narcotics are not well borne in respiratory embarrassment as a rule. Chloral should be avoided, but *if pain be excessive* a hypodermic injection of morphine does *more good* than harm, notwithstanding that theoretically morphine is contraindicated. It should not be given later than the first few days of the illness. The pain may also be relieved by poultices, which, however, are of doubtful use if carelessly made, or by application of ice. Cold packs applied to the trunk only, and frequently repeated, are very useful in relieving both pain and fever. Depressant antipyretics are to be avoided.

"A Type I antiserum is useful in Type I infections, but not in others."—(Wheeler and Jack's *Handbook of Medicine.*)

9. For an infant of two months, Winters advises the following:

Take the upper eleven ounces from a quart of milk, 16 hours after milking.

Milk-sugar, about 7½ teaspoonfuls.
Lime-water, 4 ounces.
Filtered water, enough to make one quart.
Quantity at each feeding, 3 ounces.
Eight feedings, at 6, 8:30, 11 A. M.; 1:30, 4, 6:30, 9 and 12 P. M.

10. *Marasmus* is a nutritional disorder, and occurs independently of any constitutional disease, as tuberculosis or syphilis, in which diseases, of course, an extreme condition of wasting is seen. The principal causes are bad hygiene and improper feeding.

Treatment: Hygienic treatment is important, and consists in daily bathing, massage with oil, warm clothing, and, if the temperature is subnormal, external heat by hot-water bottles, etc. The principal treatment is the institution of proper feeding. When practicable, wet-nursing will be the best means of giving nourishment, but in cases in which this method cannot be used, a properly modified milk diet must be given. No medicines internally are of any use in marasmus, but any indications should be properly met, and it is well to begin the treatment by giving, for 2 or 3 days, mercury in small doses to clear out the intestinal tract.

℞. Mercury and chalk, Sodium bicarbonate, Sugar of milk, } gr. ij each, gr. xij.

Mix and make 12 powders, and give 1 every 2 hours until 4 are taken, repeating daily for 3 days, and giving every morning following about ½ a teaspoonful of magnesia dissolved in milk or water.—(Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

11. MEASLES.—*Symptoms:* After an incubation period of from ten to fourteen days the disease is manifested by a chill or chilliness, fever ranging from 101° to 102° F., muscular soreness, headache, and intense nasal, pharyngeal, and laryngeal catarrh. There are present also intolerance to light, redness and watering of the eyes, sneezing, and coughing. On the second day the fever remits to rise again on the fourth day, when an eruption of small, dark red, velvety papules arranged in crescentic groups appears on the face and soon spreads over the entire body. The catarrhal symptoms still persist. The eruption is attended by itching and more or less burning, and about the ninth day begins to fade and disappear entirely by bran-like desquamation. All the symptoms then gradually ameliorate. Koplik's spots (a peculiar eruption consisting of small irregular spots, of a bright red color, with a bluish-white center, which appear on the mucous membrane of the lips and cheeks on the first day of the invasion) are said to be pathognomonic.

"*Treatment:* Isolation, rest in bed, and protection from drafts and from bright light are necessary from the onset of the disease. It is often desirable to give a diaphoretic mixture. The bowels should be kept regular by means of some mild laxative. The diet should be semisolid. Mild cases require no medicines. Cool sponging or the following will reduce the temperature when it becomes alarmingly high:

℞ Tinct. aconiti .....mij to iv
Spts. ætheris nitrosi.....mx to xv
Liq. potas. citrat. q. s. ad f 3j

M. S.—Every two hours.

"Daily inunction of cold cream, cocoa-butter, eucalyptol in petrolatum, and similar oily substances will serve to relieve the itching of the eruption. Camphorated oil rubbed on the chest and applied to the nose and neck aids in lessening the catarrhal symptoms."—(Hughes' *Practice of Medicine.*)

12. *Four complications of gonorrhea:* Epididymitis, periurethal abscess, stricture, gonorrheal ophthalmia.

State law relative to venereal diseases (in West Virginia): All physicians are required to make a report of all cases of gonorrhea, syphilis and chancroid occurring in their practice.

OBSTETRICS AND GYNECOLOGY.

1. *Synonyms for obstetrics:* Midwifery; maieutics.

2. *Immediate dangers of abortion:* Hemorrhage; sepsis.

Remote dangers of abortion: Sepsis; endometritis; uterine displacements; subinvolution of the uterus; sterility; subsequent abortion.

3.

FOOT.	HAND.
This is at right angles to the leg.	This is a straight line with the arm.
The inner border is thicker than the outer.	Both borders are of equal thickness.
The toes are short and are in a straight line.	The fingers are longer, and the thumb is at right angles to the other digits.
The great toe cannot be altered in its relation to the remaining toes.	The thumb may be bent across the palm, and thus brought into contact with the other fingers.
The toes cannot be separated to any great extent.	The thumb and first finger may be considerably separated.
The malleoli and heel (projecting os calcis) may be felt.	There is an absence of such features.
The ankle-joint is not freely movable.	The wrist joint is quite movable.

—(Dorland's *Obstetrics.*)

In the *knee* presentation, the flat patella may be felt; there are also two tuberosities with an intervening depression; abdominal palpation will show that the fetus is in a more or less vertical position.

In the *elbow* presentation, the sharp point of the olecranon will be felt, with a depression on one side; there are also two lateral prominences; abdominal palpation will show that the fetus is in a transverse position.

4. In a labor delayed by weak uterine contractions, the forceps should be applied when there is any sign of either exhaustion of the mother or asphyxia of the fetus. Of course, the cervix must be dilated and the membrane must be ruptured. Pituitrin has been recommended.

5. The induction of premature is sometimes indicated when the children of previous pregnancies have been still-born from excessive development. Herman advises that in these cases the patient should be examined fortnightly during the last two months of pregnancy; and if the length of the uterus equals or exceeds thirteen inches the patient should be advised that she may go to term and be delivered by cesarean section, or have premature delivery done at once. The patient should be told that cesarean section done under favorable conditions had the advantage of certainty of a living child without any appreciable risk to her own life.

6. By the term *mechanical phenomena of labor* is meant the way in which the fetus descends through the parturient canal, and the various movements and forces concerned in the same.

7. The term *external genitals* includes: Labia majora, labia minora, clitoris, urinary meatus, the orifice of the vagina, and the mons Veneris.

8. *Structures contained between the folds of the broad ligament,* are: The Fallopian tube; the ovary and its ligament; the organ of Rosenmuller; connective tissue; uterine artery and veins; nerves.

9. *Dangers of the use of the uterine sound:* Sepsis, hemorrhage, perforation of the uterus, and induction of abortion.

10. *Varieties of perineal laceration:* First degree, or superficial; Second degree, which extends more deeply but does not involve the sphincter ani; Third degree, in which the sphincter ani and the rectum are involved.

11. *Causes of enlargement of the ovary:* Inflammation, infection, prolapse, tumor, or cyst of the ovary; pelvic congestion; peritonitis; abortions; frequent pregnancies; and gonorrhea or other septic conditions.

12. METRITIS is inflammation of the body or parenchyma of the uterus. *Causes:* Wounds, injuries, operations, gonorrhea, septic infection, puerperal sepsis, cold during menstruation, intrauterine medication, and manipulations.

ENDOMETRITIS is inflammation of the mucous membrane lining of the uterus. The *acute* form is due to the introduction of septic bacteria. *Chronic* endometritis may accompany numerous pathological uterine conditions, but is generally due to gonorrhea.

BULLETIN OF APPROACHING EXAMINATIONS.

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	S. W. Welch, Montgomery	Montgomery...Jan. 11

ROENTGEN-RAY FINDINGS WITH THE DELINEATOR IN CASES OF PYLOROSPASM.

BY MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL,

AND

THOMAS SCHOLZ, M.D.,

VISITING ROENTGENOLOGIST TO THE MONTEFIORE AND LEBANON HOSPITALS, NEW YORK.

PYLOROSPASM occurs in adults much oftener than is generally believed. The constriction of the pyloric end of the stomach may be of an intermittent character, the spasm taking place for longer or shorter periods of time, or it is permanent and then might finally cause a palpable thickening of the pylorus.

Etiologically, we distinguish two types of pylorospasm, the idiopathic form and the secondary form. The latter is by far the more common, while the former occurs very rarely.

The secondary form has as its cause usually an organic lesion, either near the pylorus or in organs situated at some distance from the same. This organic lesion may lie within the stomach itself, for instance, gastric ulcer or gastric carcinoma; or the factor causing the spasm may be outside of the stomach, for instance a gall-bladder lesion, duodenal ulcer, appendicitis, neoplasm of the colon, etc.

The clinical symptoms are not always very characteristic, so that the diagnosis of the condition often appears quite difficult and is sometimes entirely impossible.

At its very beginning the presence of pylorospasm is usually overlooked. In more advanced cases the patients complain of pain in the epigastrium, radiating sometimes to the right side of the abdomen. Sometimes vomiting occurs. More or less pronounced gastric retention may, in fully developed cases, complete the clinical picture.

In very severe forms of pylorospasm peristaltic restlessness of the stomach is encountered and the pylorus may occasionally be palpated and felt as a smooth oval tumor. If ischochymia is fully developed the suffering is great and the picture of the disease resembles that found in an organic stricture of the pylorus.

Clinically the differential diagnosis between pylorospasm and organic pyloric stenosis sometimes is very difficult. In pyloric stenosis of an organic nature the motility test will always show food retention in the stomach. In beginning pylorospasm, which condition usually is of intermittent character, moderate retention will be found at one time and no retention at other times. In permanent pylorospasm retention will always be present.

In cases of an organic stricture of the pylorus the duodenal bucket will never pass through the pylorus, not even after previous application of antispasmodics. In cases of spastic pyloric obstruction, however, it will pass through the pylorus, especially after the application of an antispasmodic. In order to determine whether the bucket has reached and passed the pylorus, one sees whether the lower end of the string shows a golden-yellow or greenish-yellow discoloration. Such being the case proves definitely that the pylorus is passable. This, however, holds good only when but a small part of the string presents the above discoloration. Discoloration of one-half to one-third of the string, the full length of which is about 75 cm., means that regurgitation of bile into the stomach is taking place. In such a case one could not draw any definite conclusions in regard to the permeability of the pylorus by this test.

The best proof of the presence of pylorospasm is the direct measuring of the lumen of the pylorus by means of the pyloro-dilator.[1,2] If one finds in such a case that a balloon of about 60 mm. in circumference or more can be pulled through the pylorus, it means that a real narrowing of the pylorus does not exist. In making this test one has, of course, to apply atropine or papaverine. The instrument is then introduced in the same way as the duodenal tube and left *in situ* over night.

Roentgenologically very little attention was first paid to the diagnosis of pylorospasm. More interest in this subject was aroused by the work of Glaessner and Kreuzfuchs.[3] But even now this pathological condition is not given by the roentgenologists the importance it really deserves. We think that the *x*-ray findings in pylorospasm are of such importance that every roentgenologist should familiarize himself with this symptom complex and keep the possibility of the presence of this condition in mind during every examination of the gastrointestinal tract. Many an unnecessary operation could so be avoided, because it is a well known fact that not infrequently at the operation a perfectly normal pylorus is found in cases in which a definite roentgenological diagnosis of an organic lesion at the pyloric end of the stomach had been made. We believe that in the majority of these cases the condition of pylorospasm is responsible for the discrepancy between the roentgenological and the operative findings.

A full understanding of the radiographic aspect of this spastic condition would therefore help the roentgenologist in avoiding a wrong interpretation of *x*-ray findings concerning the pyloric end of the stomach.

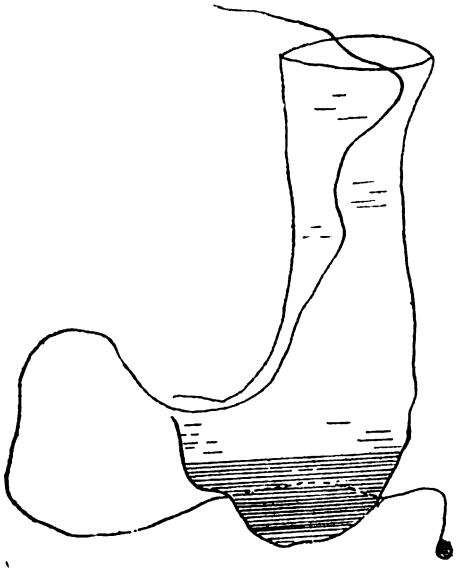

FIG. 1.—Dr. P.: Normal course of delineator along stomach, pylorus, and duodenum. Note even outline of the string.

The radiographic findings in cases of pylorospasm consist, on the plate, in a narrowing of the barium shadow along the pyloric portion of the stomach. This narrowing may involve only the extreme end of the stomach or may be evident along a larger part of the pars pylorica. In this latter case the condition might also be called a partial gastrospasm. The constriction may be very slight and evenly outlined, or it may be very marked, showing deep indentations along the contours of the narrowed portion. This condition may be permanent or intermittent, in which latter case neither the plates nor the fluoroscopic examination will show any abnormality if the examination was made during a free interval.

The fluoroscopic findings in cases of pylorospasm present more interesting features and of a greater variety than those observed on the plate. We notice first the narrowing of the pyloric portion of the stomach as described above. The peristalsis is very active above the constricted area. Toward the pyloric portion the peristaltic waves gradually become shallower. In cases where the entire pars-pylorica is involved the antrum peristalsis is absent. If one continues the fluoroscopic observation for a longer period of time one may be fortunate in seeing the constriction of the pyloric end giving way and the barium mixture entering the duodenum apparently unhindered. In these less advanced cases, the increased peristaltic action may compensate the periodical interference with the pyloric mechanism so that the gastric motility may be found to be normal. If the fluoroscopic examination is made during a free interval the findings may be entirely negative as stated above.

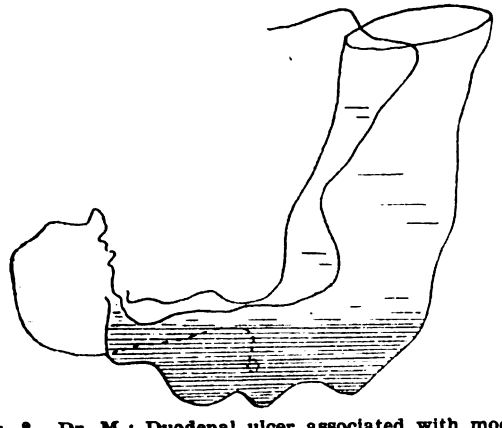

FIG. 2.—Dr. M.: Duodenal ulcer associated with moderate pylorospasm. Note irregular outline of delineator at pyloric region.

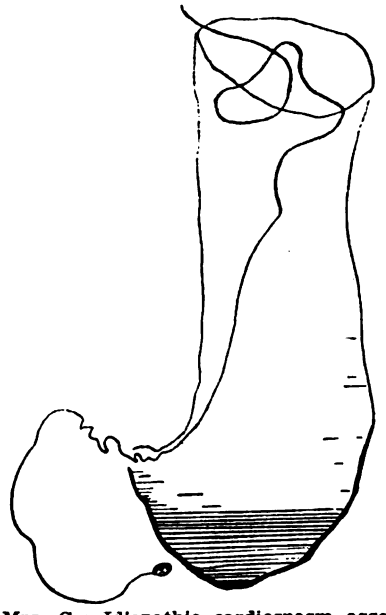

FIG. 3.—Mrs. G.: Idiopathic cardiospasm associated with marked pylorospasm. Note zigzagging of string along pylorus.

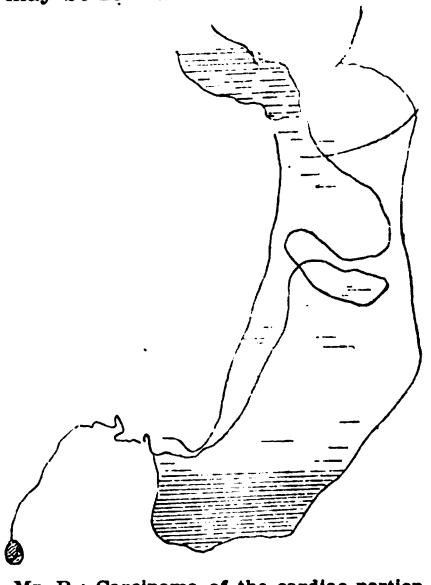

FIG. 4.—Mr. P.: Carcinoma of the cardiac portion of stomach and lower end of the esophagus associated with pylorospasm. Note abnormal course of the delineator string along the pylorus, and partial obstruction at lower end of esophagus.

In fully developed cases of pylorospasm a correct interpretation of the fluoroscopic findings is

much more difficult. One notices a more or less complete and permanent constriction of the pylorus, associated sometimes with narrowing of the entire pars pylorica. There is marked hyperperistalsis above the constricted part. Toward

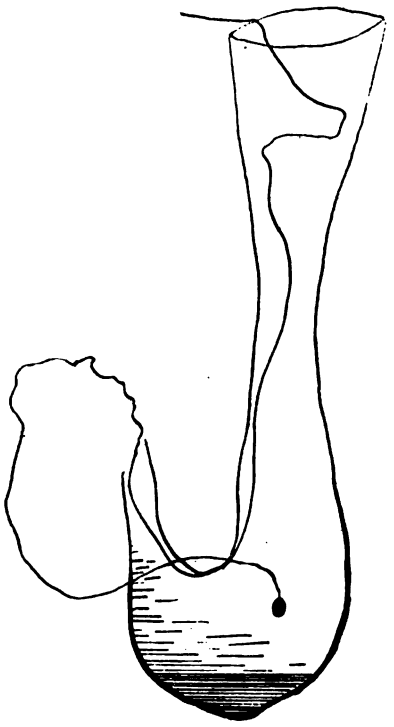

FIG. 5.—Mrs. G.: Cholecystitis with moderate pylorospasm. The uneven course of the delineator along the pylorus is definite.

the pylorus, the peristaltic waves gradually become shallower. Antrum peristalsis is greatly diminished and very often entirely absent. Notwithstanding the marked hyperperistalsis, one sees only occasionally very small amounts of the contrast meal pass into the duodenum. The six hours' examination therefore practically always shows more or less pronounced residue in the stomach. Antiperistalsis is never observed. This latter finding has never been pointed out and yet it could very well be used occasionally for differential diagnostic purposes. If one is fortunate enough in observing, during prolonged fluoroenough in observing, during prolonged fluoroscopy, a moment during which the spasticity of seen functionating normally, then the diagnosis in such a case is settled.

Roentgenologically the differential diagnosis between pylorospasm and organic pyloric stenosis is sometimes more difficult than clinically. We will understand this better if we briefly review the screen findings in fully developed cases of pylorospasm: constriction of the pyloric end sometimes associated with more or less marked narrowing of the entire pars pylorica, hyperperistalsis, tenderness over the pylorus, six hours residue. This roentgenological symptom complex almost necessarily leads to the *x*-ray diagnosis of an organic lesion at the pylorus. This explains the early desire of the roentgenologists to find some means which would aid in avoiding *x*-ray diagnostic errors in these cases. Holzknecht and Sgalitzer[4] and many others have applied antispasmodics prior to the *x*-ray examination. Holzknecht and Fujinami[5] tried to make use (fluoroscopically) of the physiological experiment, namely, that water passes unhindered through the spastic pylorus, while it is held back in cases of organic pyloric stenosis. Neither one of these methods, however, was a definite success.

During our recent studies regarding spastic conditions at the cardia and their diagnosis by means of the delineator[6] it occurred to us that the same instrument which was of such diagnostic help in cases of cardiospasm might possibly be of similar help in the diagnosis of pylorospasm. Bearing in mind the probability that the *x*-ray findings with the delineator in cases of cardiospasm will repeat themselves in cases of pylorospasm, we applied the delineator in many cases of gastrointestinal and gall-bladder lesions. It was then found that, similar to the findings in cases of cardiospasm, the string of the delineator shows an irregular course along the spastic area in pylorospasm.

We take the liberty of first presenting a few of the characteristic pictures showing the course of the delineator along the pylorus in the normal individual and then in cases of pyloropasm (Figs. 1 to 8). The underlying disease in these cases was such that spastic conditions at the pylorus could be expected.

On these plates we see the string of the delineator enter the stomach at the cardia. Then its course runs in a more curved or even looped fash-

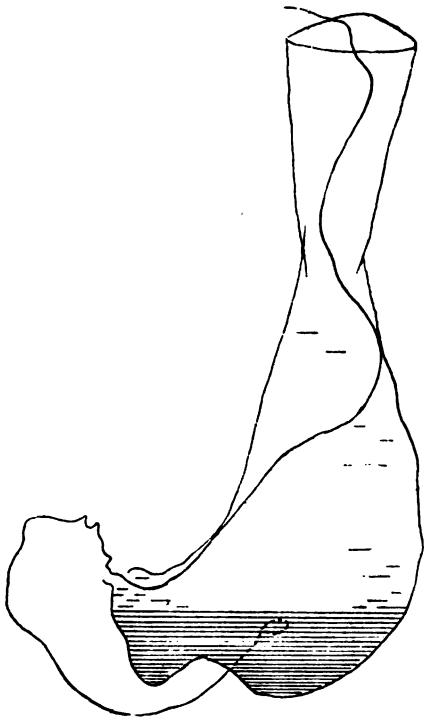

FIG. 6.—Mrs. L. G.: Appendicitis with modern pylorospasm (as proved by operation). Note irregular course of pyloric portion of the string. Roentgenological evidence (in the usual way) pointed strongly to organic lesion of the pylorus.

ion toward the lower part of the lesser curvature and along the lesser curvature through the pylorus. Afterward it follows the duodenum.

Under normal conditions the course of the string of the instrument *in situ* presents a more

or less curved line according to the individual position of the organs. This line, though curved, is even, without any irregular indentations or zigzagging. If there is a spastic condition at the pylorus, however, the course of the delineator along the spastic region becomes irregular. The degree of this irregularity corresponds to the degree of spasticity, so that one may observe the greatest variety of deformities in the course of the line of the delineator, from a fine wavy appearance to the most pronounced serrate form.

Indications.—As this our new method is usually employed for the purpose of differentiation between pylorospasm and organic pyloric stenosis, its application, as a rule, is preceded by the routine *x*-ray examination of the gastrointestinal tract. If the roentgenological findings point to a possibility of a pathological condition of the pyloric region and if the character of these findings is such that they just as well could be explained on the basis of a pylorospasm, the use of the delineator method would be indicated. If, for instance, the routine *x*-ray examination in a given case reveals evidence pointing to a pathological appendix and one finds outside of that some constriction of the pyloric end, localized tenderness over the pylorus on fluoroscopy, and moderate gastric residue 6 hours p.c., the use of the delineator will be of great help in determining the nature of the above roentgenological findings of the stomach. The findings with the delineator in cases of spasticity are so striking that it is advisable to use this new method in all those cases in which the presence of pylorospasm is suspected.

Technique.—It is best to introduce the delineator in the evening and to leave it *in situ* over night.

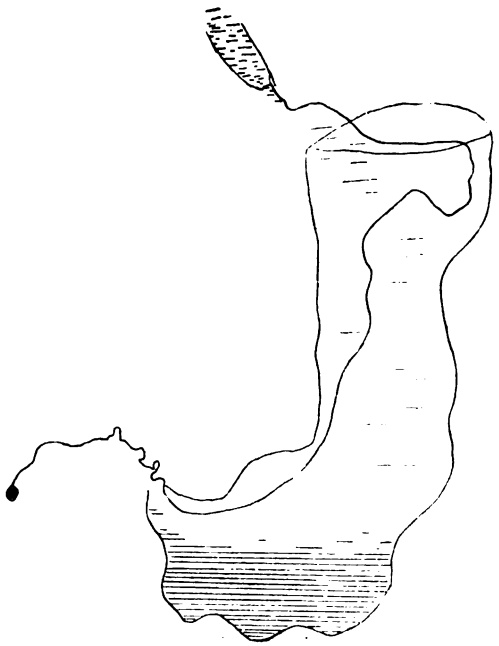

FIG. 7—Mrs. R.: Idiopathic cardiospasm with very marked pylorospasm. Note irregularity of string at the pylorus and constriction at cardiac end of esophagus.

The roentgen-ray examination then takes place on the following morning. One determines first fluoroscopically whether the metallic ball of the instrument has passed the pylorus or not. For that purpose the patient swallows a small amount of barium mixture. After the contrast mixture has reached the lowermost pole of the stomach one can very easily see whether the ball is beyond the pylorus and if so, how far it has proceeded into the duodenum. Is the patient thin,

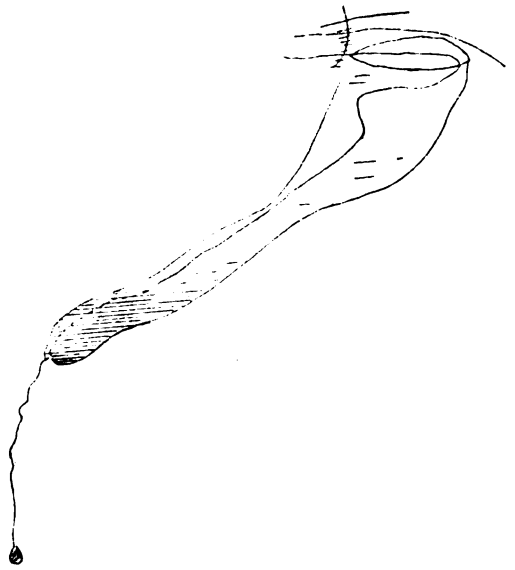

FIG. 8.—Mr. A. H.: Chronic cholecystitis with periduodenal adhesions associated with pylorospasm. The irregular course of the delineator beyond the pylorus is evidently due to the presence of periduodenal adhesions causing spasm.

one may even fluoroscopically notice the wavy course of the string along the pyloric region in case of pylorospasm, especially after light massage over the abdomen or after a slight pulling forward of the instrument. In heavier patients it is necessary to take plates in order to demonstrate the irregularities of the string. The string being very thin, the shadows on the plates are so faint that they are not favorable for reproductions.

In cases of very advanced pyloric obstruction, it is advisable to apply an antispasmodic when introducing the instrument. If on the following morning the fluoroscopic examination shows the metallic ball of the delineator still in the stomach, the obstruction evidently is of an organic nature.

Advantages of This New Method.—It can be used in any desired case without causing undue discomfort to the patient. It furnishes a much finer test regarding the tonus of the wall of the pyloric region than the barium meal, because the very thin string of the delineator reacts much more readily to changes of the tonus of the pylorus than the less yielding barium mixture. We can, therefore, by this method demonstrate those less pronounced spastic conditions of the pyloric region, which may not noticeably influence the outline of the barium shadow and yet give rise to clinical symptoms.

DIAGNOSTIC METHODS IN EXOPHTHALMIC GOITER, WITH SPECIAL REFERENCE TO QUININE.

BY ISRAEL BRAM, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR IN CLINICAL MEDICINE, JEFFERSON MEDICAL COLLEGE.

IN the presence of the four cardinal symptoms the diagnosis of exophthalmic goiter or Graves' disease is obvious. But, as in the case of such diseases as tuberculosis or carcinoma, to await the obvious in this affection is to court disaster, often to the extent of forfeiting the patient's recovery. In other words, the time elapsing between the occurrence of the prodromal symptoms of exophthalmic goiter and the frank assertion of the disease (be it weeks, months, or a year or more) through the four classical symptoms in a given case, is the period when the institution of necessary treatment does the most good. To treat early is to prevent permanent damage to vital structures and to be forearmed against morbid tissue habit; it means the maximum success in therapeutic effort. It is here that diagnosis plays a vital rôle; and the earlier the diagnosis, the more likely and speedy the cure.

The most constant symptoms occurring in exophthalmic goiter are those referable to the circulatory and nervous systems. Heart hurry, with or without palpitation, may exist many weeks before the patient is aware of it. Becoming pronounced, tachycardia is usually associated with precordial discomfort and dyspnea on slight exertion. It is for the relief of the latter two subjective symptoms that the patient applies to the physician in most instances, if he seeks medical aid early in the disease. The pulse rate is observed to vary from 90 to 120 or more per minute, and is characterized by its constancy, *i.e.*, it is not materially reduced by sleep or by the administration of digitalis even in the maximum doses. Dermographia, considered by Solomon Solis-Cohen' and others as a state of vasomotor ataxia, though a cutaneous phenomenon, is really of vascular origin, and is always present at this time.

Concomitantly with the foregoing manifestations the typical tremor may be observed. On requesting the patient to extend the arms forward and to stretch out the fingers, the tremor, in which but one or more fingers of each hand may participate, may surprise the subject by its presence. It is of the "intention" type, making eight to twelve cycles per second; tremor of the outstretched toes may coexist. The function of the central and peripheral nervous systems is quickened in varying degree, as evidenced, on the one hand, by the alert mentality, yet diminished ability for sustained attention, the emotionalism, change of disposition, and insomnia; and, on the other hand, by a heightening or increase of reflexes and the excitability of the gastrointestinal tract (as seen in the indigestion, nausea, vomiting, diarrhea), the urinary system (as observed in the polyuria), and the cutaneous system (as evidenced by hyperidrosis and the commonly observed skin lesions).

The time of occurrence of exophthalmos varies widely. While in some patients a slight stare of the eyes, lending an appearance of fright to the physiognomy, may appear quite early, in others a degree of obvious exophthalmos may occur when the disease has moderately advanced, and in still another class of patients exophthalmos occurs late in the affection or may be entirely lacking as a constituent of the syndrome. Moreover, bulging of the eyes may be unilateral, or it may be bilateral and of greater degree on one side than on the other. The various classical eye signs—Stellwag's, Von Graeffe's, Moebius', Kocher's, Dalrymple's—are nearly always associated with the exophthalmos.

The occurrence of goiter is subject to even greater variations than exophthalmos. While the first symptom to attract the attention of the patient to the neck may be a sudden mysterious tightness of the collars usually worn, although there has been a loss of bodily weight, on the other hand, demonstrable goiter may occur late in the disease, even after the circulatory and nervous phenomena and exophthalmos have been well established. Indeed, in not a small percentage of cases of extreme hyperthyroidism we find no evidences of thyroid enlargement. We may assume that in at least a fair percentage of cases of this sort there is a hyperplasia of one or more of the so-called accessory thyroids,' so often discovered at autopsy. However, definite goiter formation is observed in from 60 to 80 per cent. of cases of primary Graves' disease, occurring fairly early in the course of the affection. The thyroid swelling is of hyperplastic vascular nature, possessing characteristics which are almost pathognomonic. It is rarely massive; there is usually a moderate uniform enlargement involving the isthmus and to a lesser extent the two lobes, the right being frequently more prominently involved than the left. In the presence of marked cardiac involvement the mass is seen to throb with the cardiac cycles; it is soft and yielding, frequently somewhat tender to the touch, and a systolic thrill is usually felt. Auscultation reveals a harsh, loud systolic and occasionally also a diastolic bruit, more easily heard over the isthmus than the lobes. These evidences of extreme vascularity of the thyroid are rarely if ever present in any other form of thyroid swelling, constituting an important fact in differentiation from the simple or nontoxic forms of goiter.

As implied, to await the occurrence of goiter, exophthalmos, or both, before venturing a diagnosis in a given case is to lose valuable time for the patient. The frequency with which patients are met who, without goiter and exophthalmos, otherwise prove to be rather advanced cases of the disease, should serve to warn us against an insufficiency in diagnostic methods and procrastination in the institution of the necessary treatment. Presented with an atypical case of this sort, we must with reasonable certainty exclude the various other causes of heart hurry, tremor, dermographia and nervousness, and such conditions as neurasthenia,

hysteria and the psychoses, nervous indigestion, pulmonary tuberculosis, diabetes mellitus, paroxysmal tachycardia, chorea, and other conditions characterized by one or more symptoms which simulate clearly or vaguely any of the manifestations commonly observed in exophthalmic goiter. We must bear in mind, however, that the very conditions we are endeavoring to exclude may actually coexist with exophthalmic goiter, having asserted themselves some time prior to, concomitantly with, or during the course of the Basedowian syndrome. In such an event, the difficulties confronting the diagnostician are increased, and correct diagnosis may suffer further delay.

Of course, confronted with a patient presenting goiter as the chief complaint, it is of paramount importance to differentiate between the hyperplastic and nonhyperplastic forms of thyroid enlargement. We have already suggested in brief the local differential features. Without delving into minute details of clinical differentiation, when asked by the student to state the difference between a patient suffering with a nontoxic goiter and one with a hyperplastic or primary toxic variety, my response is: "In the absence of such complicating phenomena as pressure symptoms or carcinomatous degeneration, the former patient, excepting the disfiguring mass or goiter, is entirely well; nothing else ails her; she has had this mass for years, as a rule, and it is the only complaint. The patient with the *hyperplastic* goiter, however, complains little if at all of the neck; the thyroid swelling is of relatively recent occurrence and is slightly or moderately enlarged, it is least of all the seat of subjective symptoms; however, *the entire body* is undergoing changes incident to increased basal metabolism, and all the organs present subjective and objective phenomena incident to the existing degree and duration of thyroid toxemia."

But despite our experience and diagnostic acumen, we occasionally meet with a patient in whom a definite or final diagnosis is indeed difficult. This is especially true of (1) the so-called "fruste" or fulminating cases; (2) those presenting the Kraus or Kocher "goiter heart"; (3) the secondary toxic or "Basedowified" goiter; (4) the uncommon symptom-complex in many respects resembling Graves' disease, but in reality due to an irritation of the cervical sympathetic ganglia[3] by chemical, biological, or mechanical agencies; (5) instances (with or without nontoxic goiter) in which heart hurry, tremor, and nervousness occur on the slightest provocation, especially in the doctor's presence, and which are really congenital or acquired peculiarities of the individual. It is in these cases that we frequently resort to certain diagnostic tests, mentioned below, and though the latter are by no means infallible, their combination with historical data and careful physical examination may lead to deductions sufficiently accurate for all practical purposes.

1. It has been pointed out by Kocher[3] and others that the blood in patients suffering with Graves' disease presents a leucopenia at the expense of the neutrophile polynuclear leucocytes, and a relative increase in lymphocytes. As the blood in other thyroid affections shows the same findings, this blood picture as a diagnostic test is of only relative value.

2. The thyroid extract test has been exploited in many quarters.[4] Parenthetically it must be observed that though an exception may be noted in which an isolated case of exophthalmic goiter improves under thyroid opotherapy, we must by no means permit this to influence us in favor of thyroid extract in the treatment of the disease, nor even in its use as a diagnostic test, for obvious reasons. The administration of thyroid extract to a patient already suffering with thyroid toxemia nearly always aggravates the symptoms. It is for this reason that it has been administered in specified dosage at stated intervals during three or four days or longer, in order to observe whether existing symptoms are aggravated, or vague symptoms rendered clearer. This test is mentioned merely to be condemned, for not only is its reliability as an accurate and useful supplement in diagnosis called into question, but a hyperthyroidism formerly more or less latent may be whipped up to become very active and malignant in its course.

3. The administration of digitalis even in massive doses exerts no material influence upon the tachycardia of the disease. As a therapeutic test, in the absence of gastric irritation, this is practically devoid of harm. This test, however, is not reliable, for its data refers to the heart rate only. Moreover, digitalis administration is also futile in most instances of paroxysmal tachycardia.

4. Complement-fixation tests[5] have been described, but they are still in the experimental stage.

5. It has been shown that 100 gm. of glucose fed to a normal person does not produce hyperglycemia in one hour. A reading of over 1/10 of 1 per cent. represents a hyperglycemia when tested with a fasting stomach (McCaskey.)[6] McCaskey, Janney,[7] and others have pointed out that hyperglycemia is present in hyperthyroidism, but it can be demonstrated also in diseases of the other endocrine organs. The hyperglycemia test, then, is merely supplementary to or corroborative of deductions already reached.

6. The basal metabolism test as described by Means and Aub,[8] Tissot,[9] Boothby,[10] DuBois,[11] McCaskey,[6] Snell, Ford, Rowntree,[12] and others, is a valuable aid in diagnosis. In health, under conditions of rest of body and digestive organs, we find by calorimetry that the basal metabolism rate bears a practically constant relation to the surface area, "the rate thereby becoming mathematically a function of the body surface, while in many diseases metabolism is fundamentally deranged, the basal metabolic rate ranging far above or below normal" (Snell, Ford, and Rowntree). While variations in basal metabolism may be observed in other affections, eminently in diabetes mellitus, pituitary disease, and under the influence of caffeine, it is in diseases of the thyroid that the greatest changes are observed. Thus, the differential diagnosis between toxic and nontoxic goiters, between early cases of Graves' disease (*formes frustes*) and the neuroses, and between general endocrine imbalance and conditions not involving the endocrines, is rendered clearer than has heretofore been possible. By the basal metabolism determination we not only ascertain the severity of a case of exophthalmic goiter but we obtain some idea concerning its course. However, in order to be accurate, frequent readings are necessary, for the rate in exophthalmic goiter

often varies from day to day, and a given reading is dependable only for the time the observation is made. This test as a routine procedure is still unavailable in most quarters, as the necessary apparatus is intricate and costly, and requires the attention of an especially trained staff of individuals to make the observations."

7. If one cubic centimeter of an extract of posterior lobe of pituitary body is injected hypodermatically, there is slowing of the pulse within two minutes, passing off in seven or eight minutes. In normal persons the pulse is accelerated by this injection, attains its maximum in five or six minutes, and returns to normal within fifteen minutes. This test was first described by Bondouin and Porak (quoted by McCarrison),[14] and is fairly reliable in confirmation of diagnosis.

8. The Goetsch test[15] is easily performed and may be employed with some advantage in all cases which present an element of doubt in diagnosis. Eight minims of a 1:1,000 solution of epinephrin are diluted with an equal quantity of sterile water and injected hypodermatically into the arm. In the presence of hyperthyroidism, there is immediately formed an area of blanching around the point of injection, and about the margin of this, usually a red areola gradually shading off into the surrounding tissue. In about half an hour the center of the white area becomes bluish gray to lavender, and at the end of about one and a half to two hours the red areola takes on the bluish or lavender color, while that in the center disappears. This lavender areola remains for about four hours from the time of injection and is the most characteristic part of the test. The reaction in a normal person lasts from thirty to forty-five minutes, but in one suffering with thyroid toxemia (either primary or secondary) the phenomenon lasts from one and a half to two and one-quarter hours. Accompanying the local reaction may be an increase in pulse rate, with palpitation of the heart and an exaggeration of the tremor and nervous symptoms in general. The heart rate is increased from 10 to 50 above its former rate. In half an hour there is a moderate fall followed by a secondary rise and fall, the normal point being reached in about ninety minutes. In addition, there is a variable increase in the tremor, asthenia, throbbing, and apprehension. Vasomotor changes, such as a sudden pallor of the face, lips, and fingers, due to vasoconstriction, are followed within thirty minutes by a stage of vasodilation with flushing of the skin and sweating. A slight rise in temperature and polyuria are also observed. It can be seen that the adrenalin test depends upon an aggravation of symptoms for its interpretation. Though the Goetsch adrenalin test has been used with asserted success in many quarters, with but 5 per cent. of error, recent reports seem to diminish the value of this test in diagnosis. At the thirty-fifth annual meeting of the Association of American Physicians, Peabody, Sturgis, Tompkins, and Wearn, in a paper on this subject, remarked that the chance for error in the use of this in diagnosis is so great that it is rather dangerous to place reliance on this test. The test was positive in 14 per cent. of 28 medical students and in 48 per cent. of 103 soldiers without evidence of organic disease but with the symptom complex of "effort syndrome." Among hospital patients it was found that 17 per cent. of 17 patients with organic heart disease, and 57 per cent. of 21 patients convalescent from acute infection, gave positive reaction. On the other hand, quite a large percentage of cases of unquestionable hyperthyroidism gave negative results with this test.

9. I now propose to describe a procedure which I term the quinine test. This I have developed and employed with satisfactory results over a period extending from July, 1917, to July, 1920, inclusive, embracing a series of 160 cases, 67 of which proved to be instances of thyroid toxemia. The utility of this diagnostic measure compares very favorably with the other tests herein described, and because of its simplicity and harmlessness in application, it is perhaps the most practicable to the busy practitioner.

The peculiar tolerance to quinine by sufferers from malaria and from such febrile conditions as pneumonia, the acute tonsillar diseases and other infectious processes, must not be construed as a state of natural immunity from the effects of the drug, but as a temporarily altered condition of the bodily reactions, to return to normal on the recovery of the patient. These instances of tolerance are, of course, easily determined and need not detract from the reliability of the quinine test in hyperthyroidism.

The administration of quinine to persons otherwise normal but possessing a susceptibility to its effects, or the administration of large doses of quinine to average individuals results within from a few hours to a few days in a sensation of fullness and roaring in the head, tinnitus, and impaired hearing, with occasional impaired vision, headache, insomnia, and sometimes hematuria, purpura, erythematous areas and subdermal swellings. At times, there is seen a rash which is with difficulty distinguished from that of measles. Where extreme susceptibility exists, even minute doses of quinine give rise to uncomfortable symptoms which, in the average person, would require large doses to produce, though fatal quinine poisoning is practically unknown.

Subjects of thyrotoxemia are exceptionally tolerant to quinine administration during the course of the disease, and for a long time, usually years after the cessation of the thyrotoxemic process. In fact, this toleration to the drug in moderately large doses practically amounts to an immunity. No ample reasons for this phenomenon have been advanced. Is it because the thyroid toxin in the blood exerts a neutralizing or modifying influence on the quinine, depriving the latter of the potentiality for producing the syndrome of symptoms known as cinchonism? Is it the presence of the increased basal metabolism in thyroid toxemia that in some way produces this immunity to cinchonism? Is it because of the peculiar state of vasomotor instability and arterial relaxation in this disease that the drug is so well tolerated and usually taken with advantage? Or is it a combination of these suggested factors that obtains in explanation of this interesting fact? These and perhaps other questions with reference to this phenomenon remain to be answered conclusively; meanwhile, observation proves that doses of quinine which would almost invariably produce at least head and ear symptoms in average per-

sons are taken with impunity by patients whose thyroid output is excessive.

The technic of the test is simple, and, as implied, depends upon the immunity of subjects of hyperactive thyroid to the untoward effects of quinine administered in moderately large doses. The patient is given a dozen capsules, each containing ten grains of the neutral hydrobromide of quinine, with instructions to take one capsule four times a day, to be washed down by an ample quantity of lukewarm water, an hour or two after meals and at bedtime. By the time thirty, forty, or fifty grains have been taken by persons whose thyroid function is not excessive, there develops a sense of fulness in the head, impaired hearing with tinnitus, often dizziness and headache, and occasionally a feeling of slight gastric and bladder discomfort. Persons possessing a degree of susceptibility or idiosyncrasy will experience these symptoms after the first or second capsule; while those to a degree tolerant may not complain until sixty to one hundred grains have been taken. In the presence of a hyperactive thyroid, no symptoms develop from the daily administration of quinine hydrobromide even if given during a period of weeks or months; on the contrary, improvement in the Basedowian syndrome is frequently observed. In these patients, though gastric disturbances may constitute an element in the primary complaints, the administration of this dosage is apt only occasionally to aggravate slightly the gastric condition. If combined with proper gastric sedatives, however, this objection is overcome.

The hydrobromide is employed because it is the most acceptable of all the quinine salts and may be handled in larger doses without producing extreme discomfort in a patient whose thyroid gland does not functionate excessively. Also, the effects of this drug in negative patients wear off more promptly than other forms of quinine. In the series of cases herein mentioned, none of the untoward symptoms experienced by non-hyperthyroid patients persisted beyond several days after the discontinuance of the drug.

In this series the quinine test was employed more for the sake of determining its availability as a test than to assist in establishing the diagnosis, as in approximately 90 per cent. of the cases the nature of the affection was clearly established by means of the usual clinical methods prior to the administration of the quinine. In passing, it may be well to remark that in the performance of this test in children, smaller doses of the drug should be used. In this series, though the ages of the patient varied between 16 and 62 years, the dosage of quinine administered was uniformly ten grains four times a day. The weight of these patients varied between 94 and 205 pounds.

The cases examined were as follows:

Diagnosis.	Number of cases.
(a) Nervous indigestion, incipient pulmonary tuberculosis, hysteria and neurasthenia	16
(b) Simple adenoma of thyroid	33
(c) Cystic goiter	19
(d) Mixed adenomatous and cystic goiter	11
(e) "Goiter heart" (types of b, c, and d, chiefly substernal, with pressure symptoms)	12
(f) Malignant goiter (secondary degeneration of simple nontoxic goiter)	2
(g) Secondary Basedow or "Basedowified" goiter (toxic adenoma)	17
(h) Basedow "Fruste" (early Graves' Disease, with and without thyroid swelling)	21
(i) Well-defined exophthalmic goiter or Graves' Disease	29
Total number of cases in which quinine test was made	160

The least tolerant to quinine administration were those in (a), excepting the three patients with incipient pulmonary tuberculosis who were not troubled with head and ear symptoms until after a drachm was taken. The others in (a) were obliged to discontinue somewhere between the taking of the second and the fourth capsules (20 to 40 grains). Patients of class (b), (c), and (d) were able to take on an average of five capsules, the individual tolerance varying between 30 and 80 grains. Two showed a mild erythematous rash which disappeared soon after the discontinuance of the drug. Those of class (e) were rather less tolerant to quinine, most of them experiencing headache, tinnitus, and dizziness before the fifth capsule was taken. The two patients in class (f) were rather old, weak, and somewhat feverish, and since they were already complaining of head and ear symptoms due to pressure and induration of the neoplasm, the quinine was discontinued after the administration of the third capsule, and no deductions were made. Patients of classes (g), (h), and (i), 67 in all, each a subject of thyroid toxemia, presented no untoward symptoms after taking the twelve capsules, excepting a slight increase in gastric discomfort in a few who formerly complained of nausea and vomiting. The usual head and ear symptoms were not experienced.

CONCLUSIONS.

1. In a certain percentage of cases, the diagnosis of exophthalmic goiter is very difficult without the assistance of a reliable laboratory test.

2. The thyroid test should never be employed, for obvious reasons.

3. The Goetsch adrenalin test may be fairly reliable, though open to errors in interpretation. The danger of a flaring up of symptoms must not be ignored.

4. The basal metabolism determination is not of great value as a *diagnostic* test in exophthalmic goiter; its findings are applicable to other affections, eminently diabetes mellitus, the chronic febrile diseases, and other endocrine disturbances. It is highly useful, however, as a means of informing us of the status of metabolic equilibrium in a given patient and serves to assist with differentiation between toxic and nontoxic adenomata. As a supplement in the diagnosis of Graves' disease its value is limited to the determination of the degree of thyrotoxemia.

5. The quinine test seems valuable and quite reliable because of its simplicity in application, its harmlessness, and the fact that it does not require

an especially trained individual to make the observation. Though there may be a 5 per cent. to 10 per cent. error in its use, it is especially commendable since its interpretation does not depend upon an aggravation of the symptoms of hyperthyroidism, but there is rather an improvement of the Basedowian syndrome in many instances.

The writer is making further observations in this direction, to be detailed in a later report. He would invite others interested in this field of work to employ this test with a view to a confirmation of its virtues.

THE PRACTICE OF MEDICINE AS A VOCATION.*

BY WILLIAM J. MALLORY, A.M., M.D., F.A.C.P.,
WASHINGTON, D. C.

THE present is an opportune time for calling attention to the importance of the practice of medicine as a vocation. The more thorough our understanding of the science upon which the art of medicine is based, the more satisfactory and successful will be our efforts to heal the sick. But in other domains than medicine it has certainly been demonstrated that science without art, that strength without sympathy may not only be sterile of good results, but asbolutely harmful.

The tendency at the present time is to deny all authority, to level all distinction, and to abandon all dignity. I wish to enter a word of protest against this tendency and recall to physicians some of the spirit of the early "practitioners" and even of the much reviled "medicine man." Primitive people distinguished men whom they had chosen for a special vocation by some ceremony, usually symbolic in character, designed to impress upon both the public and the candidate the fact that one was set aside for a peculiar service, with characteristic privileges and obligations, and for the rest of his life this man was marked and distinguished by some means as being chosen for a special work.

*President's address, delivered before the Washington Medical and Surgical Society.

From the time when the student receives his diploma, his aims and ideals must differ from those of other men. Even though he may live and work for material gain, service must be the master word of his policy. It is true that he may yield to the desire of an ignorant and vicious clientèle and prostitute his knowledge and talents, but if acting on this low level does not thwart his purpose, it will certainly deprive him of his richest reward, namely, the good opinion of his colleagues and the knowledge of having acting according to his higher ideals. No matter how intimately related to industry or the State, the physician's work will ever remain largely pastoral in character, that is, he will be the guide and friend of his patients. There is not a crisis in life where the touch of the wise physician is not needed.

Prenatal influence has for some time been the subject of study and investigation and the result has been shown to be beneficial to mother, child, and the race. In the prevention of infectious diseases great benefit has been achieved and the work is still in progress. The reduction of morbidity by the application of the laws of hygiene has contributed largely to the happiness and efficiency of workers. The rehabilitation of those injured in industrial life, as well as in war, is now receiving the serious attention of both Federal and State governments. The relation of crime to mental diseases is a subject which the psychiatrist has brought prominently before the jurists and the public, with the result that a much more intelligent attitude is taken with a view to the removal of the cause and the prevention of crime, rather than punishment. The relation of physical diseases to crime is equally important and I can recall more than one case of psychoneurosis and psychosis that disappeared after the removal of a focal infection.

These examples are sufficient to illustrate the fact that the function of the physician is to assist man in making an adequate adaptation to his environment at every step in life. This, obviously, consists in much more than simply relieving a physical injury. It includes guidance in overcoming a handicap of whatever kind, and this involves some understanding of the mechanism of human behavior.

I can remember that as a student I began the study of medicine in the hope that I would be led to comprehend these very problems of human nature and conduct and would not only have the personal satisfaction for myself but would be enabled to advise others in problems of the greatest importance. But with Omar Khayyam, the Tentmaker, I must say that

> "Myself, when young, did eagerly frequent
> Doctor and saint, and heard great argument
> About it and about, but evermore came out
> By the same door as in I went."

This cynical quotation does not express the spirit of medicine at the present time for, although, in the language of Gautama the Buddha, "Veil after veil will lift but there must be veil upon veil behind," the spirit of sympathetic and intelligent investigation will lead us step by step in the right direction. "Within thyself delivery must be sought. Each man his prison makes."

So, in this relation of physician to our fellowmen,

I would mention first, the principle of integrity. The old tradition of a privileged communication should be maintained. If we, as physicians, are to understand the various complex problems which our patients present to us, we must deserve their implicit confidence that their secrets will never be divulged. As the Preacher hath said, "If thou hast heard a word, let it die with thee and be bold. It will not burst thee."

As a second guiding principle I would name sympathy. I should like to remind you that the two men, Jesus and Gautama, who have influenced human action and thought to the greatest degree, both as to affecting the largest number of people and for the longest period of time, were not only wise, but acted wisely and with profound sympathy towards their less enlightened brethren. The great Prince Gautama, a founder of Buddhism, nearly 500 years B.C., when he became aware of all the pain and suffering in his kingdom, as Sir Edwin Arnold so beautifully expresses it, "wept with all his brothers' tears, his heart broken by a whole world's woe." He had wisdom and sympathy and to-day his disciples number four hundred and seventy million. It is related of him that when a young mother brought to him her dying child for treatment the great teacher replied, "Yea, Little Sister, there is that might heal thee first, and him, if thou couldst fetch the thing, for they who seek physicians bring to them what is ordained. Therefore I pray thee find black mustard seed, a tola, only mark, thou take it not from any hand or house where father, mother, child, or slave hath died." Of course the search was vain but the mother found that "bitter balm"—she realized that she grieved not alone. So, even with the modern physician, there are many ills that cannot be cured, but the dispensation may be accepted in such a manner that a cheerful readaptation may take place and the sufferer may be enabled to live and work cheerfully, though not free from suffering.

To any one who assumes direction of others in a crisis of life, as a physician often must, imperturbability is essential. Osler has well described this virtue. He says:

"Imperturbability means coolness and presence of mind under all circumstances, calmless amid storm, clearness of judgment in moments of grave peril, immobility, impassiveness or, to use an old and expressive word *phlegm*. It is the quality which is most appreciated by the laity, though often misunderstood by them; and the physician who has the misfortune to be without it, who betrays indecision and worry and who shows that he is flustered and flurried in ordinary emergencies, loses rapidly the confidence of his patients. In full development, as we see it in some of our older colleagues, imperturbability has the nature of a divine gift, a blessing to the possessor, a comfort to all who come in contact with him. You should know it well for there have been before you several striking illustrations, whose example has, I trust, made a deep impression. As imperturbability is largely a bodily endowment, I regret to say that there are those who, owing to congenital defects, may never be able to acquire it. Education, however, will do much, and with practice and experience the majority may expect to attain a fair measure. The first essential is to have your nerves well in hand. Even under the most serious circumstances the physician or surgeon who allows 'his outward action to demonstrate the native act and figure of his heart in complement extern,' who shows in his face the slightest alteration expressive of anxiety or fear, has not his medullary centers under the highest control and is liable to disaster at any moment. . . . In the second place, there is a mental equivalent to this bodily endowment which is as important in our pilgrimage as imperturbability. Let me recall to your minds an incident related of that best of men and wisest of rulers, Antonius Pius, who, as he lay dying, in his home at Lorium in Etruria, summed up the philosophy of life in the watchward *æquanimitas*. As for him about to pass *flammantia mœnia mundi* (the flaming ramparts of the world), so for you, fresh from Clotho's spindle, a calm equanimity is the desirable attitude. How difficult to attain, yet how necessary in success as in failure! Natural temperament has much to do with its development, but a clear knowledge of our relation to our fellow creatures and to the work of life is also indispensable. One of the first essentials in securing a good-natured equanimity is not to expect too much of the people among whom you dwell. 'Knowledge comes, but wisdom lingers,' and in matters medical the ordinary citizen of to-day has not one whit more sense than the old Romans, whom Lucian scourged for a credulity which made them fall easy victims to the quacks of the time, such as the notorious Alexander, whose exploits make one wish that his advent had been delayed some eighteen centuries. Deal gently, then, with this deliciously credulous old human nature in which we work, and restrain your indignation when you find your pet parson has triturates of the 1000th potentiality in his waistcoat pocket, or you discover accidentally a case of Warner's Safe Cure in the bedroom of your best patient. It must needs be that offenses of this kind come; expect them and do not be vexed."

Little of the life of the average individual is spent among the high mountains of adventure. By far the greater part of life must be on the workday level plane, but without the patience which shall enable us to perform the routine task thoroughly and completely we shall be unprepared for the high adventure when it presents itself. This is particularly true of the physician's relation to his patients. It sometimes seems as if the natural forces with which we have to deal deliberately lay snares for the careless. Without patient, persistent attention to detail we may be found treating a symptom of a single organ simply because it is the most obvious part of a clinical picture. The large number of insidious diseases that masquerade under slight symptoms are a constant menace to the man of superficial observation or incomplete investigation. We deal in every instance not with a lesion, an organ, or a system, but with a highly organized individual; and to treat the disease without considering the man who has it is to ignore the most important aspect of the problem.

The biographies of physicians are rich in examples of the reward of patient investigation. Indeed, it has been truly said that the rich nuggets in the field of medical research have been mostly removed, yet further development must be the result of pa-

tient, routine investigation, with careful valuation of the findings in the light of all that we know of physiology and pathology.

"Yet we are the bondslaves of our day,
Whom dirt and danger press—
Co-heirs of insolence, delay,
And leagued unfaithfulness—
Such is our need must seek indeed
And, having found, engage
The men who merely do the work
For which they draw the wage."
—*The Wage Slave,* KIPLING.

For such work as this practically the only reward is the "knowledge of work well done." It is rare that even our colleagues are in a position to appreciate such service or to criticize its lack. As Samuel Johnson has said, "A physician in a great city seems to be the mere plaything of fortune. His degree of reputation is, for the most part, totally casual. They that employ him know not his excellence; they that reject him know not his deficiencies." We need something even more than the philosophy of St. Paul, who wrote to the Galatians: "Let us not be weary in well doing," for perseverance is most needed when we are not doing well.

Ehrlich, who has contributed so much to our knowledge of the blood, tried several times in vain to pass his examination for medical degree; but instead of surrendering in weariness or adopting an entirely different line of work, he continued his research, with the result that through his industry and perseverance he contributed so much to science that his university was later glad to honor itself by giving him his degree of Doctor of Medicine.

There is a law in physics that there is no work done without stress. Water poured out on a level will accomplish no work. It must be confined and made to break through narrow barriers before it can serve. Music cannot be produced without tension and vibration, and even the poems and songs that cheer and uplift us voice the cry of some one who has endured spiritual stress and pain. A wonderful example of what the English physician, Hinton, called the "forward ends" of pain may be found in the life of Edward Livingston Trudeau. It is doubtful whether even Koch, whose accurate scientific work did so much to place the subject of tuberculosis on a rational basis, accomplished as much in dealing with this disease as did Trudeau, though himself a victim of its ravages. You will recall that from his student days he suffered with this malady and that his whole career was physically a series of relapses and temporary recoveries. But at the time when he retired to Paul Smith's Hotel at Saranac, he did not resign himself to invalidism or moping, but observed upon himself the effects of climate and right living on the course of his disease and so founded a system of treatment that still practically dominates the therapy of pulmonary tuberculosis. His life story—what he accomplished by perseverance under the greatest possible handicap—should be an inspiration to every physician who grows weary of the day's routine. Of his struggle and work Trudeau wrote:

"As I look back on my life, ever since that day in 1866 when my brother came to me sick at Newport, tuberculosis looms up as an ever-present and relentless foe. It robbed me of my dear ones, and brought me the first two great sorrows of my life; it shattered my health when I was young and strong and relegated me to a remote region, where ever since I have witnessed its withering blight laid upon those about me, and stood at the death-beds of many of its victims whom I had learned to love. Of late it has condemned me to years of chronic invalidism, helplessness, and physical misery and suffering. And yet the struggle with tuberculosis has brought me experiences and left me recollections which I never could have known otherwise and which I would not exchange for the wealth of the Indies! While struggling to save others, it has enabled me to make the best friends a man ever had. From my patients who have recovered I have learned much, and this contact with them has brought me rewards which are priceless to me now. To look about me on those whom I have helped in the hour of need and, even though in a very slight degree, to have been instrumental in restoring many to health and active lives of usefulness, and to feel daily their gratitude and love, is a joyful heritage indeed, which endures in a world where all else passes away, and which brings some contentment and peace in hours of physical misery and discouragement."

Such a life and such a work confirm the statement of Robert Louis Stevenson, who says: "There are men and classes of men who stand above the common herd: the soldier, the sailor, and the shepherd not infrequently; the artist rarely; more rarely still, the clergyman; the physician almost as a rule. He is the flower (such as it is) of our civilization; and when that stage of man is done with and only to be marveled at in history, he will be thought to have shared as little as any in the defects of the period, and most notably exhibited the virtues of the race. Generosity he has, such as is possible to those who practise an art, never to those who drive a trade; discretion, tested by a hundred secrets; tact, tried in a thousand embarrassments; and, what are more important, Heraclean cheerfulness and courage. So that he brings air and cheer into the sick room, and often enough, though not so often as he wishes, brings healing."

We should remember our mission in coming into the presence of the sick, and, as far as is possible, cultivate an atmosphere of cheerfulness. By this is not meant an unseemly levity such as is practised by some; but we may well remember that, however grave the condition at the moment, we practically always have the knowledge and power to improve it —if not by complete healing, certainly by some degree of alleviation. It is in just this respect that we may learn something from the more primitive "medicine man" or healer.

Our advice may be wise, but unless it is given with a wise understanding of the human nature of our patient, it may be given in vain. Our advice must be clear and explicit, not forgetting to "say the proper words." See, for example, Kim, standing on the steps of the Temple at Benares, having obtained from Lama permission to work a healing on the child of the Jat, his former traveling companion. He does not say: "One every three hours and report to me to-morrow morning." but, "Take then these six; praise the gods; boil three in milk; the other three in water. After he has drunk the

milk, give him this (which was half of a quinine pill); and wrap him warm. Give him the water of the other three, and the other half of this white pill when he wakes." This was adequate treatment for malaria and worked a cure. "Gods, what wisdom!" said the Jat. Our neglect to appreciate the viewpoint and understand the feelings of our patients often nullifies our most intelligent efforts. If we desire our patients to take fresh air we must tell them how and when. A good illustration of this is found in Kipling's "Marklake Witches," where the witch doctor, Jerry, is competing with the local leech in the treatment of the Squire's daughter, who has a very fair complexion, flushed cheeks, and a chronic cough. The witch doctor says:

"You know the names of the twelve Apostles, Dearie. You say them names, one by one, before your open window, rain or storm, wet or shine, five time a day, fasting; but mind you, 'twixt every name, you draw in your breath through your nose, right down to your pretty little toes, as long and deep as you can, and let it out, slow, through your pretty little mouth. There is virtue for your cough in these names, spoken in that way. And I'll give you something you can see, moreover. Here is a stick of maple, which is the warmest tree in the wood. It is cut one inch long for your every year, and that is sixteen inches. You set it in your window, so that it holds up the sash, and thus you keep it, rain or shine, wet or fine, day and night. I've said words over it which will have virtue on your complaints." The same people who were ready to mob Laënnec for using a stethoscope, which, they said, caused them to spit blood, would carry out faithfully these directions with regard to hygiene, provided they were given in this way.

The same men who were not above giving charms and using the conjurer's patter, were not without heroism when occasion required. Mr. Culpepper, the herb doctor, in the course of his travels, coming upon a village infested with a plague, elaborated a beautiful hypothesis in which the planet Mars, the moon, and incidentally, the rats figured in a manner as puzzling as all of the pictures in Ehrlich's side-chain theory. It led, however, to a general rat catching, with very satisfactory results.

It is related that in the Colonial days one, Toby by name, did a thriving business in the sale of Indian medicine in Philadelphia, but his belief in herbs did not prevent his leaving the safety and seclusion of the Indian village near Lancaster, to return to Philadelphia to nurse those sick with yellow fever. The spirit of those old medicine men should not be reviled or forgotten. It is well commemorated in the poem by Kipling, "Our Fathers of Old," which begins as follows:

> Excellent herbs had our fathers of old—
> Excellent herbs to ease their pain—
> Alexanders and Marigold,
> Eyebright, Orrise, and Elecampane.
> Basil, Rocket, Valerian, Rue,
> (Almost singing themselves they run)
> Vervain, Dittany, Call-me-to-you—
> Cowslip, Melilot, Rose of the Sun.
> Anything green that grew out of the mould
> Was an excellent herb to our fathers of old.

As physicians we have an immediate and a remote goal. The immediate goal is the prevention or cure of disease and the alleviation of suffering; the remote goal is something far greater. We are the modern heirs of the ancient medicine man, the wise man, and the seer. A realization of this should give us a feeling tone towards life and mankind which will lift us in our actions and sympathies above the cares and worries incident to the accomplishment of our immediate purpose. As Kempf, in his "Autonomic Functions and Personality" says: "Herbert Spencer saw in the tendency of things an automatic evolution from a stage of dull gray homogeneity to a stage of ultra-varied and brilliant heterogeneity, and then on into dull gray homogeneity, to be repeated forever without end. This depressing interpretation neglects the inspiring end of the ceaseless self-refining tendency of living things and does not consider the career of the biocosmos as a whole. One feels that surely universal activity must have a perfect process of working since it has had unlimited endurance; that is, it never had a beginning. The idea of beginning is indigenous to man's awareness of his sensations. The inference that man has a truly dignified and sacred contribution to make is supported by the economies of movement and his unavoidable regret of neglect and waste. A condition of human affairs is coming when the effective strivings of the creator and reconstructor shall alone merit the dignity and respect of men. Labor will be recognized as the only sincere and sacred tribute of man to God. Art and song and play then will be felt as having an utilitarian value for the wholesome relaxation and evolution of the personality, and parasitism, wastefulness, and profligacy will be recognized as disgusting crimes against the welfare of humanity." "The whole principle of Christianity and the mechanism of conversion may be summed up in the Renunciation of Envy. The facts that are being gathered through the analytical study of the affective struggles of the insane, the sick and deformed, the oppressed and unhappy, make it evident that from out of the dismal night humanity is unvirtuously approaching the dawn of a new social era."

Upon the physician more than upon any other man devolves the responsibility of understanding men, and therefore upon him, the physician, devolves the duty of giving guidance and conscious purpose to this natural trend to better things in the individual and in the race. He is therefore something much greater than an operator using some complex instrument with precision, or a technician applying chemistry, biology, and physics to the relief of morbid conditions. He is the learned one who must sense and comprehend this imminent spirit in nature and in man, including himself. He will then work in harmony with that divinity which doth shape our ends, of which again the Buddha said:

> "It will not be contemned of any one;
> Who thwarts it loses, and who serves it gains;
> The hidden good its pays with peace and bliss,
> The hidden ill with pains."

If we are to follow in the footsteps of our illustrious predecessors, we shall need all the help and inspiration we can find. I know of no influence more salutary than that of the active medical society.

Here we mutually teach and learn. Here our darling ideas are laid before our colleagues, perhaps for praise, if they are worthy, but also, if they are unworthy of being received, to be told, in the language of Socrates, that we "have brought forth a wind egg." Then let us take unto ourselves that part of St. Paul's Epistle to the Hebrews, in which he says: "Let us hold fast to the profession of our faith, without wavering, and let us consider one another, to provoke unto love and good works, not forsaking the assemblying of ourselves together, as the manner of some is."

1720 CONNECTICUT AVENUE.

THE TREATMENT OF ALOPECIA AREATA WITH QUARTZ LAMPS (KROMAYER AND ALPINE).

REPORT OF 50 CASES.

BY HOWARD FOX, M.D.,

NEW YORK.

IN discussing a method of treatment of a self-limited disease such as alopecia areata, it is realized that great caution must be exercised before arriving at definite conclusions. The capricious nature of this affection is shown by its spontaneous cure in one case and its rebelliousness to treatment in another. In one case the hair may return in a few weeks while in another the baldness may remain for several years or even be permanent. As a rule, the last remedy that was used and the last physician consulted is given credit for effecting the cure.

Admitting the fact that in the great majority of cases of alopecia areata, the hair will eventually return spontaneously, it is generally agreed that this return can be hastened by appropriate treatment. Whatever the essential cause and rational treatment may be, the best results seem to be obtained by some form of local stimulation. Such remedies as phenol, liquor ammoniæ fortior, chrysarobin, etc., have long been used with varying degrees of success. Some of them have their disadvantages. Phenol, though often effective, cannot be used over a large surface. Chrysarobin ointment, while of value, is a very disagreeable remedy to use upon the scalp. Local stimulation of the skin may be produced by a number of agents which are rich in actinic rays. These include sunlight, the high frequency current, the Finsen, iron electrode, uviol and quartz lamps (the latter used in my cases). Of these, the Finsen lamp is impractical on account of its expense and sunlight for obvious reasons. The reaction caused by the high frequency current is too ephemeral to be of much value, while the iron electrode lamp does not appear to be powerful enough to have retained much popularity. The so-called uviol lamp (mercury vapor) is made of a special glass which emits a certain amount of actinic rays, though much fewer in amount than mercury vapor lamps made of quartz. Its ability to redden the skin is therefore proportionately less. For practical purposes the mercury vapor quartz lamps (Kromayer and Alpine types) are most satisfactory for stimulating the skin, as their action is easily controlled and their cost is not excessive.

The Kromayer lamp consists of a quartz chamber containing metallic mercury through which an electric current is passed. By tilting the lamp and "striking the arc" a light is produced, rich in actinic rays, which pass without obstruction through the quartz container. The lamp is also provided with a jacket through which a continuous stream of cold water circulates. The Alpine lamp is operated on the same principle except that it is air cooled and has a large reflector. It is suited for treating larger areas than the Kromayer lamp.

The cases described in this report were treated by either the Kromayer or the Alpine lamp, the former being used, as a rule, for localized and the latter for generalized areas of baldness. At the outset the instructions of the manufacturers were not strictly complied with, in that the skin was not cleansed with alcohol immediately before each treatment. This omission was later remedied and it became at once apparent that when alcohol was used it required much less time to produce an erythema. The patients were treated, as a rule, at intervals of one week or more according to convenience. It was aimed to produce an erythema that would remain for at least a week. At times the erythema was accompanied by vesicles or bullæ. A standard distance from lamp to skin was adopted, the time being increased later as the strength of the lamps decreased due to etching of the burner and deposit of lime and iron from the circulating water (Kromayer lamp).

My series of patients included 50 consecutive cases from private practice and the Dermatological Department of the Harlem Hospital. Of these, 33 were males and 17 females. They varied in age from four to fifty years, the majority being adults. Six of them were children of ten years or less. All were cases of alopecia areata of the scalp, no examples of the disease affecting the bearded region or eyebrows having been treated. In one patient (10) the alopecia was absolutely complete, while in five others (6, 7, 9, 22, 49) it was nearly so. One patient (30) presented, in addition to a number of patches upon the vertex, a border of alopecia extending around the scalp. Of the other cases, 14 suffered from single and 29 from multiple areas of baldness.

The duration of the disease varied, according to the patients' statements, from one week to eight years. In the majority of cases the patches were increasing in size when first seen, as shown by looseness of hairs at the borders. In the great majority of cases the hair stopped falling after one or two treatments.

Of the 50 cases treated, 27 were completely cured, a thick growth of hair entirely covering all of the bald areas. There were 12 cases classed as improved, the patches being covered by downy hair when the patients discontinued treatment (or were still under observation). Of the remaining 11 cases, which were unimproved, the majority had not been treated longer than three weeks. Four cases were still under treatment at the time of writing.

The results obtained were perhaps better than the figures would indicate. It is true that only 54 per cent. of the cases were followed until a com-

50.	T. McM.	16	6 weeks	multiple	4	4 weeks	Unimproved	Still under treatment.

plete vigorous growth of hair appeared. As a matter of fact when fine downy hair makes its appearance the battle is generally, though not always won and the patches become shortly covered with thick hair. Adding the 12 cases in which fine hair began to grow to the cases completely cured, gives a total of 78 per cent. The results were also encouraging from the fact that some of the more extensive cases (including one of almost total alopecia) were cured. In another case of total alopecia, however, in spite of fifty treatments extending over a period of four years, there was no change whatever. The average number of treatments given before a fine growth of hair was noticed was about five and the average period of time was about six weeks. After a downy growth of hair appeared, additional treatments were given on an average of once a week, until a vigorous growth of hair was obtained.

Recurrences were noted in several cases (1, 18, 23) and in a few there had also been a history of previous attacks of the disease. In one case (23)

with multiple patches, the hair was growing well after 13 treatments. A few weeks later there was a total fall of hair, including eyebrows, with spontaneous recovery two and a half years later.

A possible exciting cause of the disease was elicited in only a few cases. The most interesting case (48) was that of a man who had received a severe electric shock two weeks before the appearance of an extensive alopecia areata. One woman had recently given birth to a child and another had suffered from a "nervous breakdown." One man had "worked very hard" mentally for the preceding year. One patient was an army officer who had held a very responsible position during the war, one was a nurse who had had a very strenuous service in France, and three had recently served as enlisted men in the army.

Although the literature relating to the quartz lamps is fairly voluminous, it does not contain a great deal of precise information regarding the treatment of alopecia areata. The largest series of cases was published by Nagelschmidt[1] in his monograph "Die Lichtbehandlung des Haarausfalles." He reported in detail 104 cases treated by the Nagelschmidt type of mercury yapor quartz lamp (similar to Alpine lamp). Of his 104 cases, 80 were said to have been cured, 16 improved, and 8 unimproved. In this series, however, he omitted certain cases that were "not long enough under observation to enable us to give a positive or negative result and such who came only once and the result of whose treatment was not made known to us."

Bering[2] treated 100 cases with the Kromayer lamp and concluded that no other method of treatment could produce such "convenient rapid and sure" results. In describing the results of treatment of various dermatoses by quartz lamps, Schattmann[3] stated that by far the most favorable results were seen in alopecia areata. He treated a series of 70 cases and claimed to have attained a complete cure in most of them. He admitted complete failure in two patients with total alopecia.

Joachim,[4] who used the Nagelschmidt lamp, quotes histories of favorable cases, but does not give any statistics. He concluded that in order to obtain permanent results, it was very important to give a sufficiently long and intense course of treatment. This opinion is certainly in contrast with that of Reines[5], who appeared to fear the effect of strong reactions. In a report upon mercury vapor lamps in dermatology he stated that for alopecia areata he preferred the uviol lamp to the quartz lamp, as "with the former an overdosage (erythema dose) is not to be feared." Lederman[6] writes that his best results with quartz lamps were obtained in alopecia areata and Lüth[7] considers this disease well suited for the same treatment. Among foreign writers, most of them German, Blaschko's[8] remarks are decidedly conservative. He says in regard to alopecia areata "in view of the tendency of the majority of these cases to heal of themselves, one must guard against speaking of results when possibly the cure has been entirely spontaneous. However, there are cases where one does succeed only through the systematically applied quartz lamp in bringing about a new growth of hair."

The reports of American authors upon quartz lamps in alopecia areata are meager and based upon experience with small numbers of cases. Thus Heidingsfeld[9] reports "successful results," but adds that his observation had been "limited to a few cases and for a relatively short space of time." Clark[10] concludes from treating three cases that the Kromayer light "may be an effective means of treating alopecia areata." MacKee[11] in speaking of the Kromayer lamp, says "it is beneficial in alopecia areata." Jordan,[12] in his conclusions, mentions alopecia areata in a list of diseases in which the "Kromayer lamp (and the Alpine lamp in less degree) is serviceable." In like manner Bernstein[13] considers the Kromayer lamp "particularly adapted to the successful treatment" of a long list of dermatoses in which he included alopecia areata. "In three cases of alopecia areata," writes Wise,[14] "I failed to accomplish a cure despite the most painstaking technic." C. A. Simpson[15] says, "In alopecia areata I have had good results in more than half of my cases, which is rather a poor showing in a disease that tends to get well without treatment. I am sure I was able to hasten the growth, but that is all." A more favorable opinion is expressed by Schalek,[16] who writes, "In extensive alopecia areata I prefer it (Kromayer lamp) to any other therapeutic measure." Oliver[17] writes, "Another affection which often responds very favorably to quartz light is alopecia areata. Bald areas of long standing often show regrowth of hair after four or five exposures to this light at intervals of two or three weeks."

In conclusion I would say that the quartz lamps (Kromayer and Alpine) are cleanly and convenient agents for the treatment of alopecia areata. The results in my series of 50 cases, though not brilliant, were at least satisfactory. More than half of the patients were followed to complete recovery, while in 78 per cent. of the cases the new hair had at least begun to grow. The results were gratifying because I had never previously succeeded in following any considerable number of cases when using other methods of treatment. The patients would become discouraged too quickly and continue the usual habit of such cases of frequently changing both remedy and physician.

THE EARLY DIAGNOSIS OF GALL-BLADDER LESIONS.*

By ROYALE H. FOWLER, M.D., F.A.C.S.,
BROOKLYN, N. Y.

WHY is the early diagnosis of diseases of the gall-bladder the most desirable object to attain? Because (1) they are progressive lesions caused by infection through the blood stream, (2) early surgical treatment by cholecystectomy results in a permanent cure, (3) the mortality is thereby reduced to a minimum.

The keynote is a carefully elicited early history. It has been taught that this disease is a condition of declining years. As a matter of fact it begins early in adult life. A careful consideration of the duration of symptoms in operative cases shows that the average age when these patients were known to have gall-bladder infection was 34 years.

The prodromal symptoms of gall-bladder lesions and early stone formation are referred not to the gall-bladder but to the stomach. They are not obscure when viewed in this light.

A knowledge of the sequences of changes in gall-bladder infections is essential to correct interpretation of the inaugural picture. In a brief paper of limited scope these changes can be but sketchily portrayed. They must be intelligently correlated. The life-history of a gallstone from the original infection must be traced in so far as it is possible.

1. Infection through blood vessels: Insidious. History and location of primary focus. (*A*) Infection of gall-bladder wall or (*B*) Infection of gall-bladder contents. Infection of gall-bladder contents may be present at any stage. Unless virulent or accompanied by obstruction partial or complete, of the cystic or common duct, it may not cause symptoms other than dyspepsia. Nature by internal drainage is kind in relieving the condition mechanically when conditions permit. Hepatic and gall-bladder distress or pain increases in direct ratio to the degree of obstruction. When drainage is re-established by subsidence of inflammation and displacement of the stone, local symptoms moderate. The passage of the gall-bladder contents, bile or mucus (not stone), through the common duct may be attended with moderate pain in the region of the right iliac fossa hence the diagnosis of appendicitis may be entertained.

(*C*) Catarrh. (1) Stone forming. (2) Non calculous.

(*D*) Progressive changes eventuating in: (1) Gangrene, Perforation. (2) Hydrops, Empyema. (3) Adhesions, pericystic, etc. (4) Stone. (*A*) Quiescent. History of dyspepsia, primary focus. No present symptoms may be elicited. (*B*) Acute obstruction of cystic duct. Epigastric pain (cramp). (*C*) Prolonged obstruction of cystic duct. Epigastric pain (cramp) plus pain and soreness over gall bladder region or liver running round or through to the back. (*D*) More protracted obstruction of the cystic duct results in greater distention of the gall bladder. Referred pain at the angle of the scapula. (*E*) Permanent obstruction of the cystic duct. Hydrops or empyema develop depending upon infection of contents of gallbladder. Distress, soreness and pain over gall-bladder region and liver persist or may increase—depending upon degree of distention. Pronounced local signs and symptoms plus symptoms of general infection.

Moynihan credits Molloy with the grouping of inaugural symptoms in the phrase "gall-bladder dyspepsia." Of the surgical dyspepsias caused by lesions of the upper abdomen, gall-bladder dyspepsia is the most frequent. In this class surgery has not found such great activity because of the lack of precision in early diagnosis. Physicians have waited for the late classic picture. The old classic picture is based upon the post-mortem pathology of late complications. It is a phase of the symptomatology, improbable of failure of recognition, namely the passage of stones from the gall-bladder into the ducts, their lodgement therein, the development of jaundice, a tender tumor in the gall-bladder region, infection outside the biliary apparatus, and the occurrence of crippling adhesions.

Entirely too much stress has been laid upon gallstones. It is the infection in which we are interested. The infection may manifest itself as dyspepsia or more decided symptoms of cholecystitis.

The symptoms of these infections may be divided into two main groups. I purposely avoid "typical" and "atypical": (1) Those in which there is a more or less protracted history of symptoms referable to the stomach (gall-bladder dyspepsia). (2) Those in which the above are present for a shorter period but with added more definite symptoms referable to the gall-bladder. These mild gastric symptoms consist of distress and bloating, a sensation of upward pressure, usually after meals but also at irregular intervals, sometimes relieved by belching or regurgitation of sour material or slight vomiting. These attacks of flatulent indigestion are characteristic though mild and irregular. Some patients state they have to be careful what they eat, though the appetite is good; it may be voracious. In a somewhat more advanced stage of

*Illustrative cases from the Surgical Service, Kings County and Greenpoint Hospitals.

early gall-tract infection these patients complain of mild or severe pain in the epigastrium. It is usually dull and may be prolonged for several days when a free interval may occur.

Following these, a more or less pointed train of symptoms referable to the gall-bladder usually occur. There is prolonged mild or severe pain beneath the right costal margin, which may be diffused over the entire liver area and be sore to the touch. Pain may be referred rather indefinitely to the back or side. It is usually increased by deep breathing, exertion, or following a heavy meal. It is frequently mistaken for pleurisy and so mild as to constitute a "stitch in the side." Patients may forget to speak of the stitch in the side, as well the long history of stomach trouble extending over a period of three to six years. Patients in this stage may be particular in their diet and be more or less free from the so-called typical gallstone colic for years.

Between attacks of stomach disorder and mild pain referred to the back, side, and lower ribs, patients may be in comparatively good health. They pass through steady, prolonged, irregular attacks of distress alternating with comparative comfort.

The following selected histories from operatively demonstrated cases serve to illustrate the symptoms upon which early diagnosis may be based.

CASE I.—Serial No. 3. Cholelithiasis, 385 calculi in the gall-bladder. Cholecystectomy cure. Mrs. H., age 30, housewife, born in the United States, was admitted to the Kings County Hospital in October, 1914. The chief complaints were pain in the abdomen and back, radiating along right ribs, eructations of gas. The pain begins in the right shoulder blade, radiating to lower right ribs. Referred to right hypochondriac and epigastric region (reversal of usual picture). Temperature 97° F., pulse 70, respiration 24.

Present illness. Onset seven years ago. Six weeks following birth of her first child the patient was seized with severe pain between the shoulder blades which radiated around ribs to the front of the abdomen. She became very weak and experienced cold sweats. Pain persisted for about half an hour, when she was relieved by an injection of morphine. These attacks occurred about every six weeks for the first year and then became less frequent, occurring about four times a year. Four years ago they became more frequent, occurring every two months for a period of six or eight months. They have occurred at irregular intervals up to the present. Two attacks occurred last week. The patient states that these attacks are apparently brought on by excitement and hard work. In the intervals between attacks she feels well. She states that the pain rarely begins in the epigastric region. When it does occur first in this situation it radiates to the back. Pain has been sufficiently severe to warrant hypodermics of morphine in each attack. These relieved the pain but were invariably followed by vomiting. Fever accompanied the attacks but no jaundice was observed. Dyspepsia with frequent eructations of gas after meals and constipation have been present evanescently in moderate degree. She has consulted many physicians but without permanent relief.

November 15, wound healed by primary union, except at the upper angle. At this point there is a sinus two inches deep which discharges bile. General condition excellent. The patient was discharged and placed under care of Dr. Corwin, her physician. In report of December, 1914, stated that the wound had entirely healed and that the patient was in excellent condition.

To recapitulate: This case shows initial infection at the age of twenty-three years, the youngest in the series. The last attack six months ago followed the birth of her second child. A conspicuous feature is the initial pain between the shoulder blades, radiating forward to the lower ribs, hypochondriac and epigastric regions. An explanation may be found in the fact that this was an unusually deep lying gall bladder, though just why this fact should reverse the usual picture is difficult to appreciate. It is to be noted that, while flatulent dyspepsia was present, it was not very pronounced.

Some of my gall-bladder cases warrant the following comments:

CASE II. Serial No. VIII (abstract) common duct obstruction. Cholecystectomy.—This case records a thin, delicate, jaundiced woman of 55 who was admitted with the old classic text book symptoms. She had borne thirteen children, and first presented gastric symptoms of gall-bladder trouble at the age of forty-six, nine years before operation. This was diagnosed as gastritis, during which time she was a chronic sufferer from epigastric pain and typical flatulent gall-bladder dyspepsia. This condition apparently continued in an aggravated form for six years. The symptoms of indigestion may be properly attributed to a mild, sluggish, stone-forming catarrh. It is possible that the stone found in the common duct was originally formed in this location, but the sharp, severe pain in the gall-bladder region three years ago, followed by a slight attack of jaundice probably resulted from its passage into the duct.

Critical analysis of this case shows, then, that a probable diagnosis of gall-bladder infection could have been made years before operation, that in the six year interval which followed the onset of gall bladder dyspepsia, before severe, well localized pain in the gall region occurred, there were symptoms referable to this organ with which patient and doctor were not duly impressed. The age of the patient—forty-nine years, at that time—was sufficient indication for operation, in the face of chronic dyspepsia, of six years' duration.

CASE III. Serial No. 9. (Abstract). Stones in the gall-bladder. Perforation. Spreading peritonitis.—This case illustrates a somewhat different type in a young woman, rapid in its course, with frequently repeated, definite, acute attacks of localized pain in the gall-bladder region, without the predominating dyspepsia occurring before the initial attack, or in the interval between attacks. We observe that infection of the gall-bladder was present three years before operation, at the age of thirty-one. This patient had localized pain in the gall-bladder in all five attacks. The first attack indicated the presence of cholecystitis, the second attack in September was more severe and of longer duration. Attacks were diagnosed by her physician as acute indigestion. During the three years she presented mild, typical, intermittent symptoms of gall-bladder dyspepsia. The severe lancinating pain in the gall-bladder referred to the lower abdomen in September, was probably coincident with the slow leakage of bile and spreading peritonitis. In the last four months there were four attacks of this nature indicating chronic perforation.

CASE IV. Serial No. 7. (Abstract). Empyema of the gall bladder.—This patient showed an advanced sequel of infection in the person of an Italian woman sixty years of age. She is said to have first presented symptoms of gall-bladder dyspepsia five years before operation. There were four different attacks of increasing severity of three or four days' duration. During this period the history does not record symptoms referable to the gall bladder, but the condition might well have been suspected from the gastric symptoms, for these mild intermittent attacks, sudden and irregular, are as characteristic of gall bladder disturbance as are the so-called typic attacks which as a rule supplant them. But for the presence of heart and kidney disease in this patient, cholecystectomy would have been performed.

Stones are not formed in one attack. Repeated mild attacks of inflammation probably

result in dyspepsia, while a more severe infection manifests itself clinically as cholecystitis. There is now no doubt that the near and remote results of cholecystitis and cholelithiasis should be classed as sequels of infection. If we recognize that the initial infection of the gall-bladder (a cholecystitis) is an essential factor in the formation of stones, cholelithiasis may be considered a complication or sequel of cholecystitis, a late stage of the same infection. Pathologically, cholelithiasis is almost constantly associated with cholecystitis. It may also be said of the symptoms that clinically this is also true. Just what factors are involved in determining that infection in one case will result in one particular kind of inflammation or pericystic adhesions and in another in gallstones it is not possible to state.

About 80 per cent of cases show gastric symptoms at irregular intervals for from five to fifteen years, before the classic picture emphasized in the older text books have developed.

It is again emphasized that the late symptoms are the complications of biliary infection due to the passage of stones from the gall-bladder into the ducts—their lodgement therein, the development of hydrops, empyema of the gall-bladder, perforation and peritonitis, common duct obstruction with its attending jaundice, and the occurrence of crippling adhesions outside the biliary apparatus. It is with such findings that histories have been correlated in the past. Hesse emphasized the advanced picture drawn from the terminal pathology when he stated in 1914 that in 84 per cent of autopsy cases, gallstones had given no sign of their presence during life. Another failure to correlate early gastric disturbances with incipient lesions of the biliary tract! This, in spite of Krause's writing upon the prodromal symptoms of gallstones, in spite of Moynihan's contributions in England, of Mayo's "Innocent Gallstones, a Myth" in this country. Surely it is now time this heresy were eradicated.

Are there any pathognomonic symptoms referable to stone formation per se? No. There is no diagnostic criterion to distinguish a non-calculous from a sluggish stoneforming catarrh of the gall-bladder. There are no signs or symptoms either in gall-bladder dyspepsia or in cholecystitis which we can attribute to the manufacture of gallstones. We must therefore operate for cholecystitis if we hope to benefit these patients at an early stage. When we diagnose appendicitis, operation is accepted, but not so frequently with cholecystitis or surgical dyspepsia. Gallstones is the generally accepted diagnosis which from the lay standpoint requires operation. The public has not heard enough about cholecystitis.

Finally, in conclusion. 1. Surgical investigations have afforded opportunity for the correlation of early symptoms with incipient pathologic changes.

2. The nervous and muscular apparatus of the stomach readily respond to irritated foci near or remote from it. It may not be always possible to determine in a clouded picture the exact anatomic site of the lesion because of the intimate embryonic relations which exist between the stomach, part of the duodenum, liver biliary apparatus, and pancreas. These structures possess a common origin from the foregut, a common nerve supply and function in that they are all concerned in the process of absorption and assimilation of food. However, failing in a differential surgical diagnosis between a gall-bladder lesion, stomach, or duodenal ulcer, etc., the *x*-ray or other aids will usually clear up the doubt.

3. Viewed from the surgical standpoint the early diagnosis of gall-bladder lesions, which manifest themselves in the gastric symptoms, is not difficult if intensive individual study is accorded the patient's history.

4. Difficulty may be encountered in making patients realize the importance of operation in the early stage of gall-bladder disease. Would they prefer "to take a chance" and suffer from time to time until more urgent symptoms develop? It may be said by the laity, of the more advanced surgical mind who advocates early operation in these cases, "My goodness, Dr. So-and-So is even operating for indigestion." Little do they realize that the surgeon who diagnoses such conditions in their incipiency may be saving the patient from ten to fifteen years of distress and cancer death.

5. With the advance of education of the lay mind, patients will be willing to undergo operation for the relief of dyspepsia or early cholecystitis, and the late complications will be encountered less frequently. Gallstones only are now significant in the lay mind of a serious surgical condition. In the early diagnosis of disease of the biliary tract gallstones have no place. We should operate for cholecystitis.

280 JEFFERSON AVENUE.

APPLIED ANATOMY OF THE PELVIC BOWEL.

BY CHARLES J. DRUECK, M.D.,

CHICAGO.

PROFESSOR OF RECTAL DISEASES, POST GRADUATE MEDICAL SCHOOL AND HOSPITAL.

IN order to form an intelligent conception of the diseases of the colon and rectum, it will be necessary to review the anatomy of the terminal bowel—the sigmoid colon, rectum and anus.

The Sigmoid Colon.—This, sometimes called the pelvic colon, is the narrowest part of the colon; it is the continuation of the descending colon in the left iliac fossa; commencing at the crest of the ilium, it forms a loop, of variable length and position, across the front of the false pelvis and terminates in the rectum at the level of the third sacral vertebra. It fills the left inguinal region, and can be felt, in thin persons with relaxed abdominal walls, rolling under the fingers when empty, and, when distended, forming a distinct bulge. It varies in length, the average being about 16 inches. When the sigmoid is long, it crosses the median line, going even as far as the right pelvic wall, and then turns back a second time toward the middle of the sacrum, where it joins the rectum, thus making an S-shaped curve within the pelvis. When it is short, as not infrequently occurs, all its curves are abridged and it runs more or less directly backward after entering the pelvis. The sigmoid is surrounded by peritoneum, and is attached to the posterior abdominal wall by the mesosigmoid. When the sigmoid is lifted upward and to the right until the mesosigmoid is put upon the stretch, the intersigmoid fossa

is brought into view. The intersigmoid fossa is constant in the fetus and common during infancy, but usually disappears as age advances. As the sigmoid is lifted up and the left mesosigmoid exposed there will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, between the psoas and iliac muscles. This is the orifice leading to the intersigmoid fossa, which lies behind the sigmoid mesocolon and in front of the parietal peritoneum. The fossa varies in size from a mere dimple to a pocket which will admit the whole index finger.

These fossæ are found in the majority of cadavers examined, although in varying frequency according to different observers (Moynihan, 70 per cent). In infants it is almost always present, but in later years it becomes less constant. Adhesions and thickenings of the mesocolon obliterate the fossa. The opening of the pouch is in the line of attachment of the sigmoid mesocolon, near the inner margin of the psoas magnus. Its orifice is round or oval, with a well defined sharp edge of peritoneum, without any evident blood vessels. The intersigmoid fossa lies behind the sigmoid mesocolon and in front of the parietal peritoneum. It results from imperfect blending or physiological adhesion taking place between the left (posterior) layer of the mescocolon and the parietal peritoneum. Hernia into the intersigmoid fossa may occur. Eve (*British Medical Journal*, June 13, 1885, p. 276) records a case of strangulated hernia into the fossa, and McAdam Eccles (St. Bartholomew's Hospital Reports, XXXI, p. 177) also reports a case. Hernia into the intersigmoid fossa may occur in a normal abdomen, without previous peritonitis or abnormality of size or position of the sigmoid flexure or any part of the intestine, or it may occur where gross congenital abnormality may have been a factor.

The sigmoid, when empty, lies in the pelvis, and in women rests upon and behind the uterus, and upon the bladder in the male. When distended, it rises into the abdomen even to the unbilicus. The pelvic mesocolon is fan-shaped, short at either extremity and long in its middle portion. When the sigmoid rises into the abdominal cavity, this mesentery is doubled upon itself. This is of special interest, from the standpoint of applied anatomy, as the long mesosigmoid permits of great mobility of the pelvic colon, and hence renders this portion of the bowel more liable to volvulus. Individuals subject to habitual constipation have an elongated and attenuated mesosigmoid. The bowel loaded with feces falls over an adjoining loop and becomes twisted. The hypertrophied or impacted sigmoid may also be responsible for retroversion or subinvolution of the uterus, leucorrhea, and many other troubles to which women are subject and for prostatic and bladder troubles in men. Such conditions are all too frequently overlooked and account for many failures to get results in the treatment of the conditions named when more intelligent efforts have been crowned with success.

At birth only the terminal part of the pelvic colon lies in the pelvis, chiefly because of the small size of the infant's pelvic cavity. Beginning at the iliac crest, the sigmoid generally arches upward and to the right across the abdomen to the right iliac fossa, where it forms one or two coils and then passes down in the right pelvis into the pelvic cavity. When, to remedy imperforate anus, it is necessary to form an artificial anus, it is important to remember that although the iliac colon is in the left iliac region, the sigmoid usually lies on the right side. The sigmoid joins the rectum at an angle which may be sharp or obtuse, and there is no way of determining this angle except by inspection.

Rectum.—The rectum is continuous with the sigmoid colon and ends below in the anal canal. It is about 5 inches long, and rests in the hollow of the sacrum, from the level of the third sacral vertebra to a little below the tip of the coccyx and just behind the apex of the prostate gland. At this point the bowel bends sharply backward and becomes the anal canal. At its upper end the rectum is narrower than the sigmoid, but toward its lower terminus it is dilated to form the rectal ampulla.

Viewed from in front the rectum is seen to be regularly folded from side to side in a zigzag fashion, which results from the arrangement of the longitudinal muscle fibers. In addition to supporting the feces, these foldings greatly increase the capacity of the rectum without unduly dilating the tube.

These lateral sacculi may be greatly modified by disease. In atony of the rectum where the organ has been greatly distended, these dilations may be true diverticuli. In other cases where chronic rectitis has existed, the organ may be contracted to a narrow tube.

The anteroposterior curvatures are very marked; backward as the rectum lies in the hollow of the sacrum, forward as it follows the sacrococcygeal curve, and finally backward again at the anal canal. Knowledge of these curves is important when introducing the finger or instruments into the rectum. The curves vary in degree in different individuals, and may be greatly increased by tumors, a displaced uterus, or pelvic adhesion. When the rectum is empty, it occupies only a small portion of the posterior division of the pelvic cavity in the median plane, and at each side, between it and the lateral wall of the pelvis, is a large fossa (the pararectal fossa), which, when the bowel is empty, contains portions of the small intestine or the sigmoid. When the rectum is filled, its lateral flexures become more marked, and the gut passes out beneath the peritoneum, obliterating the pararectal fossa, and fills the greater part of the pelvis. Sometimes at the abrupt curve at the junction of the rectum with the anal canal a knuckle like projection presents immediately above the canal, as if the bowel were doubled back upon itself at this point. A distinct pouch may dip down in front. This more commonly occurs in multipara, and is evidently due to a relaxed condition of the pelvic structures and the loss of support afforded by the perineal body to this part of the gut, and to the great capacity and shallowness of the female pelvis.

At this junction of the sigmoid and rectum is an aggregation of circular fibers on the concave surface of the gut, which fibers spread out on the sides and convexity of the bowel and have been called the third sphincter. It is said that the contracture of the fibers will constrict the gut at this point. As these fibers encircle but a part of the lumen of the bowel

and do not go entirely around, they cannot be considered as a real sphincter.

The peritoneum covers the front and sides of the upper two-thirds of the rectum, lower down the peritoneum is attached only to the anterior wall of the rectum, and is finally reflected onto the seminal vesicles in the male, forming the rectrovesical pouch, and on to the posterior vaginal wall in the female, thus forming the cul-de-sac of Douglas. The lower portion of the rectum has no peritoneal covering. The greater part of the rectum lies behind or beneath the peritoneum. The level at which the peritoneum is reflected to the anterior viscus is of considerable surgical importance in excision of the rectum. This reflection is about 3 inches from the anus in the male and about 2¼ inches in the female, so that it is not desirable to remove more than 2 inches of the entire circumference of the bowel for fear of the risk of opening the peritoneum. When however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than 5 inches from the margin of the anus. If a more extensive operation is done, and the peritoneal cavity is necessarily opened, the opening is plugged with gauze until the operation is completed, and then the edges of the wound in the peritoneum are accurately approximated with sutures. In any rectal or perineal operation, anomalies of these cul-de-sac are to be anticipated. Tuttle reports a case where the peritoneal reflection was separated from the perineum by only the thickness of the external sphincter muscle.

The rectum is surrounded by a dense tube of the fascia endopelvina, which is fused posteriorly with the fascia of the sacrum and coccyx. This fascia surrounds the bowel like a net covers a gas balloon, and allows the viscus to distend.

In its upper portion the rectum is separated from the sacrum, and in the intervening space are the superior hemorrhoidal vessels, the left sacral plexus of nerves, and the left pyriformis muscle. Lower down the rectum is firmly attached to the sacrum by dense fascia, but it is not in contact with the bone. In the loose cellular tissues on either side of the rectum are the lateral sacral artery and the hypogastric plexus of the sympathetic. As the rectum leaves the coccyx there is an interval, the retrorectal space, which is filled with cellular tissue. The loose connective tissue around the rectum is sometimes the site of an abscess, the active focus of which may be located elsewhere. This form of abscess is above the pelvic diaphragm, but beneath the peritoneum, and is described as a superior pelvirectal abscess. The acute variety is generally due to ulceration or perforation of the bowel (possibly produced by a foreign body) above the level of the levator ani. The abscess may also occur above a stricture (simple or malignant) of the rectum, and more rarely follows abscess of the seminal vesicles. Chronic abscesses may also appear in this region from caries of the sacrum or from caseation of the presacral lymph nodes, or by downward burrowing into the pelvis of abscess from disease of the anterior surfaces of the bodies of the lumbar vertebræ.

Anal Canal.—This is the terminal portion of the bowel and begins at the tip of the coccyx, is directed downward and backward and ends at the anus. It is 1 inch to 1½ inches long. It forms an angle with the rectum. It has no peritoneal coat. It is surrounded by the internal sphincter, while the anus is surrounded by the external sphincter. These two muscles keep the lumen of the canal closed. The levator ani muscles hold the anal canal in its place in the pelvis. The anus, the lower orifice of the intestine, is formed of skin containing numerous sebaceous and sudoriparous glands and long hairs. While the anus is closed the external skin is thrown into radial folds by the contraction of the external sphincter, and appears as an anteroposterior slit.

30 North Michigan Avenue.

Medicolegal Notes.

Prescribing Families Remedies as a Business Not Authorized.—The Wisconsin Statute of 1917, section 435j, excepting from the requirements of a license to practise medicine the gratuitous prescribing and administering of family remedies, does not permit of the prescription of family remedies as a business.—State v. Till, Wisconsin Supreme Court, 177 N. W. 589.

Qualification of Expert—Report on X-Ray Picture.—In an action of trespass for assault the evidence tended to prove that the defendant assaulted the plaintiff and lamed his knee. Some one took an *x*-ray of the knee and sent the plate to an expert to be interpreted. The plate was returned with a report as to what the *x*-ray indicated. When the plaintiff offered the report in evidence, the trial court excluded it, but permitted him to inquire of a physician called by the defendant whether he had seen it. After the witness testified that he had seen the report, but that at that time the *x*-ray plate was broken, the court permitted counsel to ask him if any one objected to his taking another *x*-ray. It was held that if the report on the *x*-ray was excluded because it was hearsay, and not because it was incompetent, the questions were proper ones, for, since the witness had testified that in his opinion the plaintiff's lameness was the result of disease, it was permissible for counsel to show what investigation the witness made in order to qualify himself to give expert testimony, which appeared to be what counsel was doing when he asked the question.—Hughes v. Cavanaugh, New Hampshire Supreme Court, 109 Atl. 48.

Hysterical Blindness from Shock of Surgical Operation Compensable under Workmen's Compensation Act.—A claimant under the New York Workmen's Compensation Act had sustained an injury to his right eye, which made its removal by operation necessary. Simultaneously with the operation the sight of the left eye became affected, and ultimately was almost totally lost. No injury appeared to have been done to the eyeball, the optic nerve, or any physical thing constituting a part of the organ of sight. Yet distinguished physicians were agreed that the claimant was not simulating blindness, and in fact did not see. Dr. Neustader, chief neurologist of Bellevue Hospital, a witness for the employer, stated. "He cannot see at all." He diagnosed the trouble as "traumatic neurosis" or "hysterical blindness," and said: "This psychic shock, the surgical operation which produced the shock, was the primary means of producing that hysterical blindness." The New York Appellate Division held that the blindness was a compensable disability caused by accidental injury. The court said: "It is not important that the claimant has an uninjured physical equipment with which he should, but cannot, see. After all, a man sees with his brain, not with his eyeball or his optic nerve, and if an operation performed upon an eye so affects the mind, the nerves, or even the imagination, that a man genuinely loses vision with the other eye, then the faculty of sight has been more directly attacked than when assailed through the mechanical contrivances by which it functions."—Weber v. George Hayes Mfg. Co., 181 N. Y. Supp. 140.

New York, November 27, 1920.

THE CRUSADE AGAINST TUBERCULOSIS.

IN the program of the National, State, and local tuberculosis associations of this country for 1921 two features of particular interest to physicians are being incorporated. The first of these relates to increased medical research on tuberculosis. The amount of research being carried on in the field of tuberculosis at the present time is apparently small as contrasted with that in other related fields. To be sure, tuberculosis research is not as interesting nor probably as likely to produce dramatic results. It is, furthermore, extremely expensive and difficult to conduct. The number of men who are able to carry on research in this field is woefully small.

The need for more research is increasingly apparent. Such problems, for example, as an exact anatomical picture of the normal lung as being studied by William Snow Miller of the University of Wisconsin must be pursued to completion before a real knowledge of the diseased lung can be appreciated. The nutrition of the tubercle bacillus as studied by Esmond Long of the University of Chicago also opens up an avenue of approach of great interest. The migrations of the tubercle bacillus within the body from its portal of entrance to its final place of lodgment reveals a field of study that must be developed before anyone can answer with a reasonable degree of exactness the question of what translates tuberculous infection into disease. The whole field of chemotherapy is largely in the making, to say nothing of the field of immunology as it relates to tuberculosis. To further research along these and other lines the National Tuberculosis Association will from its own funds appropriate money and offer service in conjunction with experiments being carried on in laboratories in various parts of the country. Local and State organizations will also stimulate medical research in sanatoria, universities, and elsewhere.

The second problem to which the National Association will address itself this coming year is that of stimulating interest in tuberculosis both on the part of the general practitioner and in the medical schools. To put tuberculosis back into the curriculum of the medical schools and to give it the prominence that the mortality and morbidity of the disease warrants, is not an easy task. It involves overcoming in full the phthisiophobia engendered during the last two generations and it involves also the securing of proper institutional and other facilities in conjunction with teaching centers for clinical use of students and professors. To interest the general practitioner in tuberculosis and to improve his technique and knowledge of the disease as it relates to both diagnosis and treatment is a prodigious task.

Distinct efforts along both of these lines, however, are being made. The increasing development of special classes of students on tuberculosis such as the most recent one at the University of Virginia under the direction of Walter C. Klotz, and the increasing popularity of the tuberculosis consultant growing out of the experience of P. C. Bartlett of Framingham, Mass., are both contributions to the desired end. The traveling clinic and the ever-increasing number of tuberculosis and public health nurses are also bringing their influence to bear upon this problem.

While tuberculosis always will remain to some extent a specialty in medicine, the need for greater skill in early diagnosis of chest diseases on the part of the general practitioner is becoming daily more and more apparent. As another step in meeting this need the success of the opening session of the Colorado School of Tuberculosis modeled after the now famous Trudeau School for Tuberculosis augurs well for the establishment of similar courses of study in other parts of the country. The National Tuberculosis Association and the many State and local tuberculosis associations are addressing themselves actively to this problem. From December 1 to 11 the National, State, and local antituberculosis associations of the country will appeal to the medical profession and the public in general for support through the sale of Tuberculosis Christmas Seals and Health Bonds, and we are sure the public will, as heretofore, respond liberally to the call.

THE PATHOLOGY OF TRAUMATIC JOINT LESIONS.

BESIDES the lesions of the bones and ligaments which are variable and special in kind, joint pathology—and consequently treatment—should have in view two elements against which the synovial serosa must offer a defense, namely, blood and infection. Whether the condition is a simple traumatism or an open wound, an injury to a joint usually produces an extravasation of blood in the synovial sac. At present it can no longer be doubted that the blood resulting from the hemorrhage coagulates in the serosa. Of the products of coagulation some become completely absorbed without leaving any trace; these are the serum and blood-corpuscles. The fibrin in the form of either a red or white clot undergoes fibrinolysis, which is facilitated by the reactional exudate of the synovial membrane. If fibrinolysis is complete, no trace of the hemorrhage will remain, but if incomplete the fibrinous false membranes become organized, forming a permanent fibrous cicatricial membrane. These pathological products are of a nature that will disturb the func-

tions of the joint and they are probably the most frequent cause of chronic or relapsing hydarthroses following hemarthrosis.

The pathological data furnish a practical indication for treatment, and that is that every intra-articular post-traumatic collection of blood should be completely evacuated, and the most important of all is to rid the joint of the solid products of coagulation, namely, the fibrin. In closed traumatisms, particularly in hemarthrosis, a fine aspirating needle will not give exit to these products; therefore puncture of the joint with a small knife is the proper method. In open traumatisms closing of the joint should not be done until after perfect hemostasis and free irrigation of the synovial sac with a warm physiological salt solution. The successful results obtained by immediate suture of joint wounds from projectiles in war has led some to conclude that the synovial membrane defends itself particularly well against infection, better even than the soft structures. The process of local defense is, in its essence, identical in both the soft parts and joint serosa; in both the essential agent of defense is the serous exudate—the lymphorrhea. The plasma of the lymph is capable of keeping the wound sterile by preventing the growth of infectious bacteria. If this defense is more efficacious in a wound of a joint than in one of the soft parts, it is because the reactional exudate is retained in a closed synovial sac and finds in the qualities of the synovial membrane ideal conditions for retaining its fluid state; therefore its defensive properties, because the latter certainly appear to be related to the fluidity of the exudate. If for some surgical reason the joint cannot be entirely closed by sutures, an infection of the synovial membrane need not necessarily occur—on the condition, however, that surgical drainage has not been established. Every type of drainage—glass or rubber tubes, etc.—will almost invariably bring about infection of the joint serosa.

Following penetrating wounds of the knee-joint where total suture has been found impossible, the joint may be left open for days or even weeks without infection of the synovial membrane taking place; the serous exudate of the joint continually flows off and prevents the infection of the external wound from traveling into the joint. A wound of the soft parts will never act like that. If a joint defends itself efficaciously, it is on account of the abundance of the exudate and its fluidity. Such an evolution is possible only if the microbic variety will allow it and if the endoarticular structures have suffered little. When a bone has been injured the dirt incrusted within it may very readily escape the curette or chisel; minute bits of bone and acicular splinters undergo necrobiosis and become foci of bacterial growth against which the articular exudate may be powerless. Therefore, the chances of infection increase in direct proportion to the extent of the osseous lesion. The conclusion to be drawn from these data is that in osteo-articular wounds a successful outcome of the case will depend upon the thoroughness of the toilet of the wound, and whenever circumstances permit the bone focus should be excluded from the cavity of the joint.

TYPHUS FEVER.

THE severe epidemic of typhus fever now raging in Poland and Galicia must be regarded as an international danger, and there can be very little doubt that if it is not checked in the new stricken areas it will spread westward. It has been conclusively shown that the infection is carried by lice. The principal carrier is the body-louse, which anchors itself on the underclothing next to the skin and feeds twice a day. These lice can carry infection, of course, only when they have fed upon human beings already infected by typhus and have transferred themselves to a healthy human host. Whether the head-louse also transports typhus is not yet clear, but it is known to carry other types of fever. The recent activities of medical officers in London have shown a widespread prevalence of head-lice among school-children, but the cleansing of the heads does not remove the far greater potential danger arising from *Pediculus vestimenti*. The only remedy against this parasite is the immediate baking or disinfection of clothing.

Cases of typhus are uncommon in Great Britain but a few instances occur annually. The disease was endemic in Ireland until quite recently and a considerable number of cases still occur there every year. The Western regions of the Continent of Europe have long been practically free from typhus, though the disease has always been endemic in Western Russia, and to a much more limited extent in Galicia and Poland, as well as in certain areas of Eastern Germany.

Typhus fever has always been associated with war, chiefly owing to the inability of the troops to change their clothing, with the consequence that *P. vestimenti* is able to breed freely in their undergarments. Yet there has been no typhus worth mentioning as an accompaniment of war in Western Europe since the Napoleonic era. It is now considered doubtful whether the supposed outbreak during the siege of Metz in 1870 was really typhus at all. The heritage of disease left by the Franco-German War was chiefly smallpox. Typhus raged in the war zone during the Russo-Turkish War of 1877-78, but hardly a case was reported on either side during the Russo-Japanese War in 1904-5. The British troops suffered in a slight degree from typhus during the Crimean War and are believed to have brought the infection to England, thus leading to the last serious epidemics there. The worst year was 1858, when 1,062 patients were admitted to the London Fever Hospital. Central Europe has not suffered greatly from typhus since 1812-14, when there occurred the terrible epidemics resulting from the Napoleonic wars, though there was a fairly widespread prevalence of the disease again in 1846-47.

Typhus is essentially a winter disease and occurs most frequently in temperate climates, the obvious explanation being that its development is enhanced by overcrowding, bad ventilation, and close contact in dwellings. The mortality is almost invariably high among doctors and nurses. Our greatest safeguard is that typhus is now thoroughly understood, while precautions can be applied without difficulty.

PROPHYLAXIS AND TREATMENT OF RUPTURE OF THE UTERUS DURING LABOR.

RUPTURE of the pregnant uterus takes place in two circumstances. Sometimes on account of tension or an extreme thinness, the lower segment of the organ gives way, either spontaneously or from some adjuvant influence, such as the application of the forceps, but above all when attempts at version are essayed. At other times, the lower segment of the uterus ruptures as a result of operative traumatism in tentatives at rapid dilatation of the cervix or the delivery of the child through an incompletely dilated os. Uterine cicatrices, the result of former tears or operative interference, and particularly the cesarean operation, naturally create a predisposition to rupture.

Should rupture appear to be on the point of occurring, version is to be proscribed and in its stead forceps or the cesarean are to be resorted to according to circumstances. The indications for cesarean section are becoming more numerous and at the present time this operation should unhesitatingly be done in every case where rupture of the uterus appears to be practically unavoidable during attempts at extraction through the cervix. All this immediate prophylaxis is itself dominated by a more distant prophylaxis which consists in maintaining watch over pregnant women during the latter months of gestation and at the beginning of labor in order to resort to proper measures in good time, such as version in shoulder presentations. In order to avoid rupture from forced dilatation of the cervix, this procedure should be carried out with prudence and then only in properly selected cases, that is to say, in multiparous women with a yielding cervix already somewhat dilated, and extraction of the infant should not be attempted until dilatation is complete. Particular care must be exercised in cases of former tears of the cervix, which are susceptible of being the starting-point of a new laceration.

Should rupture have occurred there are three conditions to be feared, namely, shock, hemorrhage, and infection, which are to be dealt with according to the principles of modern surgery. When the rupture is complete the child and placenta are to be extracted without delay, the best procedure being laparotomy, especially if the fetus has escaped into the abdominal cavity. All other procedures are either dangerous or inefficient. Abdominal hysterectomy is unquestionably the method of choice. If the rupture is subperitoneal the fetus may occasionally be removed by the vaginal route (version must never be attempted), and this may be followed, in simple cases, by plugging with sterile gauze. But laparotomy remains the only proper procedure when the hemorrhage is in any amount or there is indication of infection, even if very slight.

Finally, there are uterine ruptures which are complicated by a tear in the bladder or by hernia of an intestinal loop through the rupture. These conditions are to be dealt with according to rational indications.

THE THERAPEUTIC USE OF METHYLENE BLUE.

IT is somewhat to be regretted that methylene blue in therapeutics has been neglected of late, although it is evident that the very numerous uses to which this drug has been put have met with varying success. It is evident that renewed researches are required in many circumstances, as for example the exhibition of this hydrocarbon in the treatment of the acute stages of nephritis, certain forms of pulmonary tuberculosis, tuberculous adenitis, hyperchlorhydria, gastralgia, etc. In these morbid processes the cases published have been too few and not sufficiently conclusive to settle the question of the efficacy of methylene blue, but it must be admitted that further assays would be highly interesting and merit being pursued. The question is quite different in those affections in which methylene blue has been used as an analgesic, antiseptic, or antimalarial. In painful diseases the good effects of the drug are unquestioned and as an anti-malarial sufficient testimony has been forthcoming to show that—although it is not a specific—its effects are sometimes equal to those of quinine. As an antiseptic this medicament has shown itself potent, and the results obtained in urethral and vaginal gonorrhea, purulent cystitis, and ocular affections are proof of this, likewise the coloring affinity of the drug for the majority of pathogenic bacteria. Therefore, it can be distinctly regarded as an excellent analgesic, antiseptic, and antimalarial. Methylene blue possesses an evident action on neoplastic tissue, but it cannot be regarded as by any means specific. In these circumstances its antiseptic action favors tissue repair and, perhaps—but this is merely an hypothesis—a special trophic action on the nerve endings allowing the epithelial structures to assume a normal growth and vitality. Thanks to this action—although as yet unexplained—methylene blue combined with curettage of the morbid structures may result in durable cure of cutaneous epitheliomata. When combined with radium application in recent cases a rapid cure may be looked for, while in old cases, with extensive tissue destruction the drug may still be preferred to excision or it can be used as preparatory to excision, which is unquestionably the procedure of choice when feasible. In cases of palpebral epithelioma with invasion of the angles of the eye, especially the internal angle, the treatment becomes a more delicate matter; it lasts longer, but the ultimate outcome is generally quite as good. Nothing is less known than the action of methylene blue on malignant neoplastic tissue, and this applies to all drugs so long as the pathogenesis of cancer remains an unknown quantity. But although this action is unknown the therapeutic results obtained can be appreciated.

LEAD POISONING FROM BULLET WOUNDS.

THERE was but little if any literature on this subject during the great war, although it is generally understood that old carriers of lead projectiles run some risk of developing plumbism. This silence may be explained in various ways. Doubtless the great majority of projectiles have been extracted or encysted, or the time may not have been sufficient for the development of plumbism, or the belated character of many journal articles, some of which

were really written long before the war closed, may have been a factor. In an article by Curschmann in a German periodical abstracted in *La Presse Médicale* for Sept. 15, 1920, xxviii, 66, it is stated that evidences of plumbism have been one of the indications for the removal of old projectiles. But a case is given which shows that such intervention may be highly meddlesome. The soldier in question was wounded in the hip in March, 1918. Eleven months later he complained of lumbar pain and was found to have albuminuria. It was found to be due to colibacillary pyelitis, but this was found later to mask a nephritis ascribed to lead poisoning. Although the ball was promptly extracted the patient died of lead encephalopathy. It was believed that the operation had mobilized fine particles of lead which had been swept into the circulation. In such a dilemma the medical man is veritably "up against it." Curschmann therefore put the matter up to the biochemist Straub, who suggested infiltration of the operative field with sulphate or bicarbonate of sodium, which should cause the solution and elimination of the lead by the urine and thereby spare the nervous system. The internal use of potassium iodide is mentioned as having the same effect, although it is not recommended in these cases, for if this salt could do the work the local soda injections would not be required.

Chemotherapy and Acid-Fast Bacilli.

Lindemberg and Pestana report in the *Brazil-Medico* for Sept. 11, 1920, xxxiv, 37, the results of experiments inspired doubtless by the curative effects of chalmoogra oil and its gynocardic acid in leprosy. The unneutralized acid in the oil seems able to inhibit the multiplication of the acid-fast Hansen's bacillus. It is thought that the rationale of the action of codliver oil in tuberculosis is the same. It has hitherto been taught that these oils act by stimulating the leucocytes in the defence of the economy, or that they are simply tonics; but such views will probably have to give way to the chemotropic or bacteriotropic hypothesis, especially as the same action is shown *in vitro*. We cannot generalize by stating that all unsaturated acids have similar properties—in other words the behavior of the acids in question is quasi-specific. We can, however, test other acids in this connection. Of interest were some experiments in which chalmoogra oil was tested in tuberculous subjects in a parallel series with codliver oil. With both drugs a reaction occurred comparable to that which follows tuberculin injections. Not the oils as such, but the acids which they contain were injected. The reaction is attributed to the death of the bacilli and liberation of toxic products. From this viewpoint the greater the number of bacilli the more pronounced should be the reaction. But in the clinic the best effects of codliver oil are seen where but few bacilli are in evidence (scrofula). In tubercular leprosy, in which vast numbers of bacilli are present, the clinical results are notably good, for the bacilli are destroyed without any evidence of toxemia. In this respect tuberculosis and leprosy show pronounced differences from the viewpoint of chemotherapy, and neither of the oils gives any promise for the future of the first named disease.

Coffee and Vitamines.

Mattei contributes an article with this title to *Il Policlinico*, Sept. 13, 1920, xxvii, 37. He sketches briefly the conception of the vitamines. Many classes of substances seem to possess vitaminic activities and among them certain derivatives of pyridine, pyrimidine, and xanthine. In experiments on pigeons infusion of coffee appears to benefit the polyneuritis of these animals. But while vitamines are destroyed by a heat of 115° C., coffee withstands a temperature near 250° C. which carbonizes it. The author found that 8 c.c. of an infusion of mocha of 5 per cent. strength were enough to suppress pigeon paralysis within a few hours' time. The weight did not improve but otherwise the animals were completely restored to health. Persistent use of coffee also seemed able to prevent the development of the disease in animals fed only on polished rice. The result was rather deceptive, however, for in from 4 to 6 weeks after apparent cure the symptoms rapidly returned and the animals perished, with symptoms of paralysis and cerebral complications. Coffee had only arrested the progress of the malady. Experiments with caffeine showed that it did not represent the full action of the coffee infusion. Other ingredients, formed probably in roasting the berry, were also active. Some of these, as methylamine, hydroquinone, pyrrol, caffeol, and furfurol are known, while others are doubtless associated with these. The active principle as stated cannot be an ordinary vitamine because of its much greater thermostability and also because it does not cause increased weight of the animals. The author fed pigeons on wheat bran as a substance rich in ordinary vitamines, giving this exclusively. The result was a steady loss of weight and it became necessary to add a few grams of rice daily in order to maintain life. Hence vitamines in excess cannot compensate for lack of ordinary combustible food.

Etiology of Senile Hypertrophy of the Prostate.

Gori gives a digest of our knowledge of this affection in the *Annali di medicina navale e coloniale* for July-August, 1920, xxvi, ii, 1-2. The affection is peculiar to old age but is not physiological, as has been claimed. Of alleged causes are venous congestion, horseback riding, sedentary life, constipation, alcoholic excesses, repeated attacks of gonorrhea, stricture (Hunter), and stone in the bladder. Zappala believed that in old age the bladder changed from a pelvic to an abdominal organ so that a kind of compensatory hypertrophy resulted which, originating in the trigonal region, later extended to the prostate. Other alleged causes are prostatitis, acute or chronic, heredity and familial tendency, arteriosclerosis, chronic affections such as gout and tubercle, and the stimulation of some hormone. It is easier to state what it is not. There is no evidence of an infection or previous inflammation and the antecedents of the victims show the greatest variation—it attacks equally gluttons and light eaters, married and single, subjects with and without venereal contamination, and is independent of the sexual life. Technically it is a fibroepithelial tumor—a mixed tumor, in fact. It is known that in adenoma there may be a tendency to form a fibrous stroma but the author turns this about by making

the fibrous formation come first as a sort of "post-climacteric" phenomenon, while the origin of the adenomatous component is unknown. However, a similar process is seen in two other sexual organs, the uterus and the breast, a fact which has some suggestiveness.

News of the Week.

Chinese Relief Work.—It is estimated that there are 20,000,000 of famine sufferers in the four Chinese provinces where the crops failed this year. Relief work has been undertaken by both Chinese and foreign organizations. The American committee to raise and distribute famine funds, organized on the initiative of the American Minister, Charles R. Crane, is directed by H. C. Faxon of the American Chamber of Commerce in Peking. H. C. Emery, formerly of New York and Washington, now in China, is treasurer of the American committee. French and British committees are being organized. The Chinese Ministries of Finance, Agriculture and the Interior have appointed a commission to dispense a $1,000,000 fund to be raised by means of a short-term loan. According to reports from Shanghai another fund of $1,800,000 has been undertaken by seven provinces at the instigation of Tang Shao-yi, the chief southern peace delegate.

Jewish Relief Agents to Russia Safe.—It was reported recently that American relief workers in Russia had been imprisoned by the Reds and their goods confiscated. Dr. Frank Rosenblatt, now in Moscow, Soviet Russia, as the representative of the Joint Distribution Committee of the American Funds for Jewish War Sufferers, sends refutation of this report. He cables that there has been no interference with the activities of American Jewish relief workers upon the part of the Soviet government.

Delegates to International Sanitary Conference. Surgeon General Cumming of the United States Public Health Service has appointed Assistant Surgeon General H. J. White and Senior Surgeon G. N. Guiteras as delegates to represent the United States at the sixth international sanitary conference to be held at Montivedeo, Uruguay, Dec. 19 and 20.

Need of Aid for Russian Refugees.—The French have estimated that 50,000 refugees from the Crimea have arrived in Constantinople, which is already crowded with thousands of refugees from Asia Minor, and that 50,000 more are on the way. Conditions on the vessels which are transporting Russian soldiers as well as those carrying refugees are said to be terrible. Food, already high, has reached famine prices, and the supply is woefully inadequate. Cable dispatches say that unless America will come in on a large scale, either officially or through the Red Cross or other voluntary associations, the situation of the refugees from South Russia will be one of the most tragic and fatal of the World War.

Dispensary for United States Employees.—The formal opening has been announced by Surgeon General Cumming of the United States Public Health Service of the public health dispensary in building "C," Seventh and B Streets, Washington, D. C. Dr. S. H. Christian is in charge. With the establishment of the dispensary in its new home the staff is prepared to furnish medical assistance to all persons injured in line of duty in any of the government departments, civilian employees of the Army and Navy, members of the police and fire departments of the District, the coast guard, the Mississippi River commission and other allied government commissions, war risk insurance patients and men under training by the federal board for vocational education.

Coal Issued on Doctor's Prescription.—When the recent cold wave struck Buffalo, N. Y., there was a shortage of coal and gas, and the stocks of oil heaters of all kinds soon became depleted. Physicians then began issuing prescriptions—so the story goes—for coal, charging one dollar per prescription. The remaining small supply of coal was going fast until the health department issued a warning against the issuance of coal prescriptions except in case of illness or for other special and valid reason.

Tribute to Florence Nightingale.—Under the auspices of the American Red Cross, France, Italy, Great Britain and the United States joined recently in paying tribute to the memory of the "Lady of the Lamp." Exercises were held at the base of the Statue of Liberty on Bedloe's Island.

Tuberculosis "Cures" Expensive.—Figures compiled by the National Tuberculosis Association show that a sum approximating $2,000,000 is spent each year by residents of New York City for fake tuberculosis "cures," and that the perpetrators of these frauds throughout the country take from their confiding victims between $15,000,000 and $25,000,000 annually. The sum extracted from residents of this city alone is six times the $350,000 which the New York and Brooklyn Tuberculosis Associations hope to raise through the sale of Christmas seals, for fighting the disease in the five boroughs.

United Hospital Fund Drive Opened.—The forty-first annual drive for the United Hospital Fund started November 15, the goal being $1,500,000. The campaign closes November 29.

State Hospitals Crowded.—In its annual report the State Charities Aid Association announces a condition of serious crowding in the State hospitals. In those near New York City the following overcrowding exists: Brooklyn, 209; Central Islip, 1,227; King's Park, 683; Manhattan, 430. Appropriations for new construction at the State hospitals passed by the Legislature last year and approved by the Governor amounted to $3,675,000, and additional construction amounting to $1,461,750 was authorized. The chief new construction of State hospitals now in progress is at the Marcy Division of the Utica State Hospital, where the State owns about 1,000 acres of farm land and is developing what will virtually be a new State institution.

Recruiting Nurses.—Owing to the impending lack of trained nurses to staff the new hospitals that are being opened by the United States Public Health Service the superintendent of nurses will make an effort during her pending tour of inspection to obtain recruits to fill the vacancies. Public Health Service hospitals exist in all parts of the country and offer opportunities for patriotic service in the care of disabled soldiers of the great war.

Tuberculosis Hospitals.—It is announced that

several of the largest general hospitals of the United States Public Health Service are being provided with special facilities for the diagnosis of tuberculosis and for the study of patients to determine which Public Health Service hospital is best suited to their needs. These hospitals will become clearing houses for the diagnosis and placement of tuberculosis patients in their vicinity, especially for those with doubtful diagnosis or with complications requiring expert care. At each of them physicians skilled in this specialty will be on duty and the most modern methods will be in use. All Public Health Service hospitals, however, are open to tuberculosis cases; and admission is never denied because of lack of special facilities. Special centers are already functioning in the Public Health Service hospitals at Fort McHenry, Baltimore, Md.; Fox Hills, Staten Island, New York; and Hospital 35, St. Louis, Mo. Other centers will be organized as soon as possible.

Ban on Whiskey Prescriptions Lifted in Chicago.—Chicago doctors who can show "reasonable cause" may now have as many whiskey prescription blanks as desired. The regulation limiting the number allowed has been withdrawn by the Government.

The Medical Society of the County of New York, at its annual meeting held at the New York Academy of Medicine, Nov. 22, 1920, elected the following officers for the ensuing year: *President,* Dr. George Gray Ward, Jr.; *First Vice-President,* Dr. Orrin S. Wightman; *Second Vice-President,* Dr. Arthur F. Chace; *Secretary,* Dr. Daniel S. Dougherty; *Assistant Secretary,* J. Milton Mabbott; *Treasurer,* James Pedersen; *Censors for three years,* Drs. Edward M. Colie, Gustav G. Fisch, Dewitt Stetten.

Second Child Health Station Opened.—The Red Cross formally opened the second of a series of child health stations to he established in the congested sections of New York City.

Drug Cache in Dingy Flat.—Narcotic drugs of the estimated value of $200,000 were discovered by detectives recently in a downtown flat in New York City. The find included two million grains of morphine, cocaine and heroin, which was secreted in tins, preserve jars, kettles, teapots and various receptacles.

Cardiac Disease Statistics.—The Federal Bureau of Vital Statistics have announced that organic diseases of the heart resulted in more deaths than any other one cause during 1919.

Weekly Health Index.—As a health index the Bureau of the Census is publishing each week mortality reports from the largest cities in the United States. There are given for each city the total number of deaths reported (stillbirths excluded), the death rate, the number of deaths under one year of age, and the proportion of infant deaths to total deaths. Where the data are obtainable for the previous five years, averages for the corresponding weeks are given for each city.

Prohibition and Coffee.—The secretary of the National Coffee Roasters' Association, which held its tenth annual meeting in St. Louis early this month, is authority for the statement that sixteen billions more cups of coffee have been consumed so far in 1920 than during the entire year of 1919. The increased consumption is attributed to prohibition.

The New York State Civil Service Commission announces, among examinations to be held Dec. 4, the following: Assistant *x*-ray operator, State Department of Health, at a salary of $1,500 to $1,800; chemist, Bureau of Food Standardization, Division of Foods and Markets, Department of Farms and markets, salary $2,150; Director, After-Care Service, State Industrial Commission, salary $2,400; Field Agent for After-Care Service, State Industrial Commission, salary $1,500; Field Agent, State Commission for Mental Defectives, salary $1,500.

The Tri-State Medical Association of the Carolinas and Virginia will hold its next annual meeting at Spartanburg, S. C., on Feb. 16 and 17, 1921, under the presidency of Dr. J. P. Munroe of Charlotte.

Dr. Morton in the Hall of Fame.—At the recent election the Hall of Fame at last made place for the name of a representative of the medical profession, Dr. William Thomas Green Morton, who first demonstrated to the world the possibilities of surgical anesthesia, being the first physician so honored.

Dr. John P. Wright has removed his office to 327 East Fifty-eighth Street.

Dr. Otto V. Huffman has removed his office to 25 East Sixty-fourth Street, New York City.

Death Rate Falls.—Statistics issued by the Census Bureau show the 1919 death rate in the death registration area of continental United States, which embraces 81 per cent. of the total population, to be the lowest recorded for any one year. The rate of 12.9 per 1,000 of population showed a drop of 5.1 per 1,000 from the unusually high rate of 1918 resulting from the epidemic of influenza. The total number of deaths in 1919 was 1,096,436, of which 111,579, or 10.2 per cent. were caused by heart disease, while tuberculosis resulted in 106,985, or 9.8 per cent., the statistics showed. Deaths attributed to pneumonia totaled 105,218, influenza 84,113, nephritis and Bright's disease 75,000 and cancer and other malignant tumors 68,551.

Obituary Notes.—DR. ROBERT C. JAMES, for twenty years a practitioner in New York City, died suddenly at his home in Lexington, Ky., Nov. 13, at the age of fifty-five. He was graduated from the College of Physicians and Surgeons, New York City, specializing in obstetrics. For many years Dr. James was on the staffs of Bellevue and Lying-In hospitals, and he was formerly an instructor in the medical department of New York University. In 1915 he returned to Lexington on account of ill health, but came back to New York a few months later to help in the emergency created by the war, ill health finally causing his retirement to his home in Kentucky. Dr. James was a member of the American Medical Association and of the New York Pathological Society.

DR. WALTER B. CHASE of Brooklyn, N. Y., gynecologist and pioneer in radium therapy, died Nov. 14, at the age of seventy-eight. He was graduated from the Medical School of Maine in 1867. He was a fellow of the American College of Surgeons and of Brooklyn Gynecological Society.

DR. DANIEL T. CONDICT, County Physician and for many years physician for the Erie Railroad, died at his home in Goshen, N. Y., Nov. 18, from effects of ivy poisoning. He was sixty-seven years old. He was graduated from Albany Medical College in 1874.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, October 29.

Strikes and Health.—There is obviously a quite intimate relationship between strikes and health. A strike on a scale such as that now proceeding in Great Britain, exerts a most injurious effect on the national health and, unfortunately, this effect is most markedly felt by the child population, that part least able to bear privations and whose value to the nation is incalculable, especially to a nation like Great Britain. With regard to this aspect of the situation, it may be remarked that strikes always fall most heavily on innocent women and children, and it is an instructive sign of the times that the women in the mining regions, speaking generally, were averse to a strike. Now that women of this country not only wield great influence but great political power, it seems reasonable to suppose that they may use this power to prevent strikes which play havoc with prosperity and which have a most adverse effect upon the health of the rising generation.

The League of Nations and the Health of the Peoples.—Professor F. F. Roget of Geneva delivered before the Chadwick Trust at the Surveyors' Institution, Westminster, on October 18, a lecture which was the first of three dealing with the Cannes Conference, and the program laid down by the Medical Department of the League of Nations. The lecturer gave a résumé of the progress made during 1919-20 in the formation of the League of Red Cross Societies, as also an account of the work to be done by the League of Health working under its direction. The lecturer said in part that the horrors of the last war had given the various Red Cross societies a great opportunity to extend their beneficent work in wartime, and in times of peace it would include promotion of the health and welfare of the peoples, the control and prevention of disease, and the mitigation of suffering throughout the world. Moreover, an effort was being made to secure humanitarian conditions of labor for men, women, and children. These benefits to humanity could be secured only by uniformity in work and by the standardization of remedies. The League of Health would create a moral bond of fellowship among all nations which Christian charity had failed to do. In the history of mankind the war spirit of the male was dominant, but it was the duty of women to destroy this idea of destruction, and women must play their part in the work of the League. An agreement was reached at Cannes that a uniform standard should be applied to the solving of the health problems of the world and that the various sections should form a central bureau of public health. The preventive section alone was composed of 22 members, America sending 5, Great Britain 6, France 4, Italy 5 and Japan 2. There were also sections dealing with child welfare, tuberculosis, venereal complaints, malaria, nursing, and statistics, all composed on an international basis. The conference, at the head of which was an executive council, met twelve times, and was now crystallized in the office of the Red Cross Society in Geneva. By its aid the health official of any town would be able to obtain all the information he would require as to cost and plans for giving to that town the best public health organization, and such a town would reap all the benefits which standardization could supply. There was also a moral and educative side in the direction of peace on earth in the combined work of the League of Nations and the League of Health. These bodies could supply information as to the evil effects of war, which would be at the disposal of all legislators, while the strict neutrality of the League would tend to dispel the prejudices fostered by national misunderstandings. Professor Roget said that the Cannes conference had initiated a Universal Health League designed to embrace all civil life in its world activities of law, charity, and science.

***X*-ray Department Opened at the Bethlem Hospital.**—The Hospital is one of the oldest charitable foundations of London and the Brothers of Bethlem were the most ancient of all the old religous orders. It is believed that in very early times they migrated westward from Bethlem itself and came to England, their mission being to look after those who were insane and who in those days were thought to be possessed of the devil. It is, perhaps, needless to say that the harsh term "Bedlam," a synonym for madhouse, which in a less understanding and sympathetic age was applied to institutions for the insane, was a corruption of "Bethlem." On October 22 the Lord Mayor of London visited the hospital for the purpose of inaugurating the installation of the apparatus for the *x*-ray department given by Sir Charles Wakefield, a London alderman and president of the institution. Dr. Porter-Phillips, the medical superintendent, gave an outline of the work which the hospital is carrying out and mentioned that the good work inaugurated by Simon Fitzmary had been continuously carried out since A.D. 1247. In the course of his interesting speech he said that with the inauguration of the hospital, or department for nervous diseases in 1919, the dawn of a new era in the history of the hospital had been heralded. A means had been thus provided which would enable the sister sciences of neurology and psychiatry to flourish side by side, which, in the field of medicine, hitherto had been studied quite apart from each other. He referred to the gift of Sir William Wakefield of one of the best and most modern installations of *x*-ray apparatus to be found in London as the coping stone of the institution.

Woman's Intuition and the Thyroid Gland.—Although the intuition of woman or rather remarks thereon, hardly comes within the scope of a London Letter which I imagine is mainly written with the object of recording medical and surgical facts, yet as intuition certainly is a phase of psychology, or the innermost workings of the human mind, it is not altogether outside the province of medicine. Sir James Barr, at the opening of the winter session of the Liverpool Literary and Philosophical Society in the Royal Institution, Liverpool, on October 6, as president, discussed the Philosophy of Immanuel Kant. He pointed out that intuition had a practical utility which Kant did not appear

to fully understand since he seemed to place the human form of it much higher than the instinct of other animals. Sir James Barr observed that intuition directed us to conceptions of life and consciousness as something more than mere functions of organized matter and yet the interdependence of life and those functions must not be overlooked. The intelligence of many human beings was improved and their lives prolonged by judicious use of the sheep's thyroid. Women were often more sharp-witted than men because their thyroid glands, as a rule, were more active.

The Menace of Typhoid in Europe.—A large number of men, women, and children have crossed and are crossing the Russian frontier on their way to Lettish territory. They are the first fruits of an agreement between Soviet Russia and the Lithuanian Government for the repatriation of 300,000 Letts within the space of two years. According to newspaper accounts most of them are swarming with vermin, and as Russia is being swept from end to end with typhus and recurrent fever, stringent measures must be put into force to prevent such returning Letts from becoming centers of infection in the districts in which they settle. So when the railway trains steam into the Lettish stations, and into Reschitza in particular, its passengers are herded into a long barrack at the entrance of the quarantine station, which has been established and equipped there by the American Red Cross Commission. They are first subjected to thorough disinfection, new clothing is issued by the Red Cross officials, and the old garments, which have stood the ordeal of disinfection, are handed over to their owners. Then they are well fed and receive blankets for use in the dormitories, where they are sheltered during the five days of their quarantine. Those in need of medical treatment are taken to the hospital. At the end of five days, if no symptoms of typhus or other diseases have shown themselves the refugees are free to rejoin their friends. About 500 persons pass through Reschitza station every twenty-four hours. Elaborate measures of this nature are essential if a desolating epidemic of typhus is to be prevented from sweeping across Western Europe during the coming winter. All along the western frontiers of Russia refugees and returned prisoners are streaming back to their own countries in a similar condition to that of the Letts. It is urged that in order to render the situation yet more secure the same kind of stations be established at all the main crossing places between Esthonia and Roumania. While the League of Red Cross Societies can procure the men and material necessary for this preventive and curative campaign, it must be borne in mind that such a sanitary cordon requires large sums of money to maintain it in efficient working order. To this end the league has entrusted an appeal throughout the British Empire to the Imperial War Relief Fund. It must be a source of pride to Americans that the American Red Cross Commission is doing the spade work necessary to preserve Europe from the awful results of an epidemic of typhus, and no doubt money enough to do the work thoroughly will be forthcoming. The health conditions in Russia point the moral that if for this cause alone, the utmost endeavors should be put forth to bring peace to that unhappy country. At present Russia is a menace to civilization from all points of view.

The Call for an Improved Milk Supply in Great Britain.—The meeting of the National Association for the Prevention of Tuberculosis which took place at Liverpool recently and which was referred to and quoted from in previous letters, brought at least one fact into desirable prominence, that is, that the milk supply of the country is in a very unsatisfactory condition. In a letter contributed to the *Lancet* October 23 last, Professor R. Stenhouse Williams discusses certain features of the milk question. He points out that the dairy farmers have formed a representative council, known as the Associated Milk Producers' Council, which has already brought forward a valuable scheme for the improvement of the milk supply. Two of the essentials of the scheme are that the dairy farmers shall band themselves together in districts, be paid for their milk according to its quality, including cleanliness, and have persons in their own employ competent to go in and out of the dairy farms and advise upon improvement of methods. In association with this scheme an attempt is being made at the present time to link up the producer, wholesaler and retailer, so that their interests in the fate of the milk may be one. All these events represent a great upheaval for the improvement of the milk supply from within the industry. Everyone interested in public health, especially in infant welfare, will welcome this movement with enthusiasm. The only matter for wonder is that steps in this direction were not taken years ago.

First Annual Report of the Ministry of Health.—This report has been issued recently and is a really remarkable document. Even if the magnificent schemes evolved from the brains of the members of the Ministry of Health never come to full fruition, a consummation, by the way, which cannot be expected, the very fact that they have been suggested is for good. This tends to educate the people and pave the way for health reforms. The masses are beginning to understand that their salvation does not lie in glib-tongue politicians, but rather with those who seek to improve the national health and thus render each individual more happy and prosperous. Sir George Newman, chief medical officer of the Ministry, is responsible for the editing of the report, which is distinctive throughout, both as regards the information it contains and its literary merits. In succeeding letters I shall refer to the report in detail.

OUR LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, November 1, 1920.

Syphilis in Nurslings.—The Pediatric Society of France has recently had a highly important discussion on the subject of the proper treatment of syphilis in nurslings, and whether or not the arsenical products should be used for them. The opinion was unanimously in favor of this practice. The discussion was opened by Cassoute and Teis-

sonnière of Marseilles, who had treated some twenty infants by injections of novarsenobenzol in the epicranial veins, which they regard as preferable to the jugular veins for this purpose, as suggested by Blechmann. The doses given were one centigram per kilogram of the infant's weight at the time of the first injection and from one and a half to two centigrams for the following injections, with a maximum of ten centigrams which should never be exceeded. Their results obtained certainly speak in favor of this method.

Renault injects the arsenical product indifferently into the jugular or epicranial veins. He believes that the proper dose is one and one-third centigram of novarasenobenzol per kilogram of the infant's weight, a dose that he has invariably employed from the onset of the treatment and with which he has never observed any accidents. As to the results of this treatment that Renault has employed during the past four years in a total of one hundred nurslings, thirty of whom were a few days to three months old, they can be regarded as very satisfactory. He noted that after the second or third injection—that is to say, in from twelve to fifteen days—the cutaneous or mucous lesions disappeared, but five or six weeks and five to six injections—are required for a cure of the visceral accidents—hepatic and splenic. When the infant can be followed for a sufficient length of time, it will be found that the evolution is normal and that the cure will be definitely established if the treatment is continued long enough.

Babonneix prefers the jugulars for the injections because these veins swell when the infant cries, while Lesué considers that it is better to give the arsenical preparation in the form of rectal suppositories. The latter are hollow and the powder is put in them at the time of use in order to avoid any decomposition of the product taking place. He advises the dose of one centigram per kilogram of the infant's weight and this is given two or three times a week. The suppository is inserted immediately after the infant has been to stool.

Institute of Legal Medicine in Geneva.—The Faculty of Medicine of Geneva is to have a new Institute of Legal Medicine, which, it is expected, will be inaugurated this month. The new building is a model of its kind. In the basement are the frigorific machines for preserving cadavers for as long a time as necessary. An elevator transports the body directly from the frigorific apparatus to the autopsy room. There are four mortuary rooms and a small crematory for anatomical débris. Next a large room which will probably be used for Roentgen ray work, a room for disinfecting, etc. On the first floor is a room for expert work, the private office and laboratory of the professor of legal medicine and another for the first assistant. There is a mortuary room in which the cadavers are exposed for identification. Next, there is the autopsy room, a room for photography, and an amphitheater with seats for one hundred students. A chemical and bacteriological laboratory, a library and pathological museum are also on this floor. And lastly, there is to be a museum containing all the articles, clothes, weapons, etc., pertaining to crimes, suicides, etc., the collection being started with all the material collected by Professor Megevaud during the past twenty-five years.

Swiss Quarantine Stations.—The conditions resulting from the war and the geographical situation of Switzerland have compelled the Federal health authorities to establish quarantine stations at several places on the Swiss frontiers for the control and detention of certain categories of travelers entering the country, and of these demobilized soldiers are the most to be feared for the spread of disease. The measures taken are directed especially against the plague, cholera, and above all typhus fever, which latter disease still ravages Oriental Europe. Up to date typhus has not developed in Switzerland, thanks to the destruction of lice by the health departments of each canton, and a strict control of boarding houses and furnished rooms. The latter is maintained, as it is in these places that the floating population lodges, among which are to be found individuals susceptible of carrying contagion or of contracting diseases. Therefore a periodical disinfection of these establishments, with destruction of lice, bedbugs, etc., is carried out.

Cholera and plague have so far remained localized to Oriental Europe and the countries directly bordering on Switzerland have not reported a single case of either of these diseases for some time past. Certain countries have been declared to be contaminated with these diseases by the Swiss Federal Council, and travelers arriving from these regions are submitted to medical observation for the necessary lapse of time.

The last disease over which quarantine control is exercised is epidemic dysentery, which still exists in an endemic state in Germany and Italy more than in other countries. According to the most recent reports received by the Federal Board of Health, this disease shows a recrudescence at present in these two countries, as is usually the case at this time of the year. Although this recrudescence is for the time being less marked than in the last few years, the affection has been placed upon the list of diseases requiring notification to the sanitary department by the attending physician.

Progress of Medical Science.

Boston Medical and Surgical Journal.

November 11, 1920, clxxxiii, 20.

1. Review of Untoward Effects Following Arsphenamine and Its Derivatives. William P. Boardman.
2. Argyrol. Walter P. Lancaster.
3. The Relation of Food to Infantile Eczema. Edward Scott O'Keefe.
4. Observations of an Anesthetist. Boris Rapoport.
5. Longings of the Pregnant, Viewed in Light from the East. Alfred Ela.

1. Review of Untoward Effects Following Arsphenamine and Its Derivatives.—William P. Boardman considers arsphenamine a very powerful drug in the treatment of syphilis, but one which may cause most serious lesions, especially of the skin, gastroenteric, nervous and cardiovascular systems, sometimes leading to death. Although some of these disturbances are unavoidable, it would seem that many of them might be averted by care in the administration and careful judgment in regard to the dosage, the intervals between the doses and the total amount given.

3. The Relation of Food to Infantile Eczema.—Edward Scott O'Keefe bases this communication upon

seventy cases of eczema as influenced by diet. The majority of these cases were seen first at the Dermatological Out-Patient Department of the Massachusetts General Hospital and referred to the Children's Medical Out-Patient, where they were studied and their feeding regulated. The cases were then treated jointly by the two departments mentioned. The plan followed included first, a general physical examination, then a careful consideration of the child's diet, or of the mother's diet in the breast fed infants, and finally, cutaneous food tests. The dietary history afforded an opportunity for the regulation of the feeding in general and also frequently gave suggestions as to possible offending proteins. In making the cutaneous tests linear scarifications were used. Only those tests showing a well defined erythema and wheal were considered positive. It was found more practicable to do the tests upon the back than upon the forearm, as is usually done in adults. All the children were under four years, and the majority were under two years of age. Of the 70 cases 41 per cent. gave a positive reaction to one or more of the food tests, 12 per cent. showed a doubtful reaction, and the remainder were negative to any of the food proteins tried. Egg proteins gave a positive reaction in 30 per cent. of the cases upon which they were used, potato in 20 per cent., casein in 16 per cent., codfish in 12 per cent., lactalbumin in 11 per cent., wheat in 9 per cent., and corn in 5 per cent. of the cases upon which they were used. The mother in no instance showed sensitization to the protein to which her child reacted. Ten nurslings were negative to the proteins of human milk. Nearly 20 per cent. of the series gave a history of asthma, eczema, or urticaria in some other member of the family. In several of the families one child after another developed eczema as soon as it was weaned. An exacerbation of the eczema was in many instances coincident with the eruption of a tooth. In the treatment each child was placed upon a diet suitable for its age. The nursing intervals and diet of the mother were adjusted in the breast fed. This included the elimination or reduction of any article in the maternal diet to which the infant was found sensitized. In the case of the other children the offending protein was eliminated from the diet if practicable. This could not be done in the instances where milk was the main or sole article of diet. Here an attempt was made to modify the milk in order to secure the most easily digestible mixture for the particular case. The intimate relationship shown to exist between food and eczema in so large a percentage of these cases justifies the conclusion that dietary regulation is essential in the treatment of this condition.

1. The Placental Gland and Placental Extract.—Samuel W. Bandler, among other phases of the subject, discusses the therapeutic uses of placental extract. The therapeutic test is supplied by the results obtained. Studying the effect of placental extract on menstruation, he found that, as a rule, the normal rhythmical menstruation function is delayed thereby several days. This action is likewise evidenced in many individuals whose menstruation, while regular, comes on at periods three to five days before the normal interval is reached. Going further into the field of pathology and considering cases of menorrhagia or even metrorrhagia, it is found that placental extract tends to diminish bleeding. Therefore, judging from his own experience, the writer takes it that placental extract not only inhibits those regular processes whereby blood is lost from the uterus, but does so likewise in many conditions simulating menstruation, even though the flow is profuse or the interval shorter than normal. Placental extract has an effect only second to mammary extract in diminishing excessive menstruation, though it lacks entirely the power often evidenced by mammary extract, of diminishing the size of the uterus, as in myomata, and it does not have a like influence in aiding involution. Carrying the therapeutic effect over into the field of pregnancy, he found that threatened early miscarriage or abortion is often averted by the administration of placental extract and thyroid extract. The various processes going on in the uterus, which are typical of normal menstruation, are practically the steps which occur in many miscarriages. Therefore, placental extract, by inhibiting these processes, furnishes added proof that it delays or inhibits the processes tending to menstruation. During pregnancy many patients are sleepy, drowsy and tired, without a suggestion of nausea, and it is presupposed that the placenta has put the posterior pituitary to sleep. Judging from the quieting effects of placental extract in those cases where the symptoms are seemingly due to pituitary overactivity, Bandler translated his observations to the realm of that phase of human instinct called the libido sexualis. Placental extract is, so far as he knows, the most valuable of the endocrines administered for the purpose of controlling or modifying this human instinct. He has no proof that placental extract in any way alters pressure within the cerebrospinal canal, either raising or lowering; but the very gratifying relief of many of the typical headaches makes him lean to the notion that it probably diminishes pressure. The writer suggests, finally, that the important factor concerning placental extract is its ability to influence the posterior pituitary and to stimulate the anterior pituitary and the adrenal cortex.

2. New Aspects of Menstruation.—James Oliver bases his discussion of menstruation on an analysis of the menstrual fluid obtained from a girl of eighteen who had never seen her menses because the hymen was imperforate. A crucial incision was made through the imperforate hymen and seventy ounces of menstrual fluid collected. The fluid as it flowed through the incised hymen presented from first to last the same appearance and was throughout of a uniform consistency. Quantitative examination disclosed the following: specific gravity 1031; water, 87.13 per cent.; solids, 12.87 per cent., consisting of organic material 95.02 per cent. and ash 4.98 per cent. Further analysis showed: serum albumin, 12.49 per cent.; serum globulin, 16.56 per cent.; mucin, 3.37 per cent., and fat, 0.0051 per cent. From his study of this menstrual fluid the writer holds that there is clearly no justification for clinging to the belief that menstrual fluid is purely and simply blood poured out by vessels which have been opened into in consequence of a degeneration and disintegration of the mucous lining of the uterus. On a secretory hypothesis alone it is possible to account for the great variation in the amount and physical characters of the menstrual fluid, and not only in different individuals but in the same individual at different times and even during the same menstrual period.

1. The Treatment of Pyelitis in Infancy and Childhood.—Kretchmer and Helmholz base this preliminary discussion on a series of eleven cases treated by pelvic lavage with silver nitrate. In boys, because of anatomic considerations, cystoscopy and ureteral catheterization cannot be carried out as early as it can in girls, although one of the writers has repeatedy performed cystoscopy on boy babies of 14 months. The value of routine roentgen-ray examination cannot be overemphasized. Doubtless in some of the cases that are diagnosed as pyelitis and in which pelvic lavage fails to produce a cure, there are factors present which explain the failure, such as the presence of calculi, tuberculosis of the kidney, and stricture of the ureter. In order not to overlook a possible renal tuberculosis, routine examination for tubercle bacilli were made, including guinea-pig inoculations from urine obtained from each kidney and bladder. In the series under consideration no evidence of renal tuberculosis was found. The youngest patient treated was 7 months of age. In this case the two ureters were catheterized simultaneously, and both renal pelves were treated with silver nitrate. The oldest child was 10½ years old. Between these the following ages were recorded: one, 1½ years old; one, 2 years old; two, 2½ years old; one, 5 years old; one, 7 years old, and two, 8½ years old. All cases occurred in girls. There were no untoward results or reactions following instrumentation and treatment. The object of treatment was to render the urine free from pus and sterile. Pelvic lavage with solutions of silver nitrate rendered the urine sterile and free from pus in nine cases in this series. All of the cases treated in this way had resisted all other forms of treatment.

5. Many Orthopedic Deformities Due to Calcium Deficiency.—Frank E. Peckham, after recalling the important part played by calcium in the human economy, states that when calcium metabolism is interfered with, there may result a deficiency, in which case the bones, muscles, nerves and ligaments are deprived of the requisite calcium. Under these conditions there may directly result scoliosis, knock-knees, bow-legs, flat feet, and other orthopedic deformities. In many of these cases there is found the history of an artificially fed baby. This usually means that the food was sterilized or pasteurized, or both. When this is done, the vitamin substance is destroyed or partially destroyed, and no substitute is as good as the real thing in fresh, uncooked milk. In this way, the writer contends, many babies are handicapped at the very beginning of life, and specialists in infant feeding persist in believing that this is the thing to do. The vitamin substance is an essential in calcium metabolism. If fresh uncooked milk, orange juice, and in many cases, thyroid extract, are administered, the difference in the result obtainable is often remarkable. The addition of lime water to all milk given is important. All milk should be tested with litmus and sufficient lime water added to render it alkaline.

7. The Pharmacology of Chelidonin, a Neglected Alkaloid of Chelidonium, or Tetterwort.—Paul J. Hanzlik calls attention to the activity and usefulness of chelidonine, an alkaloid obtained from tetterwort or chelidonium, which was formerly official in the U. S. Pharmacopeia. The actions of chelidonine resemble those of papaverine and the benzyl esters, but differ from morphine in several particulars. It possesses a relatively low toxicity. It causes depression and narcosis without subsequent excitation of the central nervous system, differing in this respect from morphine. It slows the pulse and lowers the blood pressure, owing to cardiac depression, relaxes smooth muscle in all regions, and depresses skeletal muscle without influencing the nervous connections. Therapeutically, chelidonine is indicated in hypertonus, angina pectoris, bronchial asthma, intestinal, ureteral, and uterine colic, or spasm of smooth muscle anywhere. Being obtained from a weed growing extensively in the United States, and which can also be easily cultivated, chelidonine offers a distinct economic advantage over papaverine which, at present, is virtually unobtainable. It is also more palatable than the benzyl esters.

11. The Precipitin Test for Globulin in the Arachnoid Fluid in General Paralysis.—Hektoen and Newman found, from the study of arachnoid fluids from various sources—general paralysis, epilepsy, insanity, epidemic poliomyelitis, normal persons, etc.—with antialbumin and antiglobulin serums, prepared as outlined in the paper, that in the fluid of general paralysis both albumin and globulin are increased, but principally the globulins, while in the fluid of epilepsy the increase in protein noted in their first contribution to the subject seems to be in the albumin. Antiglobulin serum obtained either by injections of human globulins or of paralytic arachnoid fluids has caused precipitates in paralytic fluids diluted from 16 to 512 times with salt solution and even higher, while in fluids from other sources it caused precipitates only in lower dilutions, dilutions of from two to eight or sixteen times, the only exceptions encountered so far being fluids from frankly inflammatory conditions. This statement covers the testing of about fifty different arachnoid fluids from undoubted cases of general paralysis, and a large number of fluids from other conditions. The writers have had no opportunity to study the arachnoid fluid of locomotor ataxia, cerebral syphilis in the usual sense, multiple sclerosis, etc. The general character of the results with different kinds of antiserum is illustrated in a table, which shows also that the most striking results, so far as general paralysis is concerned, have been obtained with the serum of rabbits injected with the arachnoid fluid from general paralytics. On account of its simplicity the test, the details of which will be published later, is well adapted to routine use.

2. An Address on the Causes of Nervous Diseases.—Ernest S. Reynolds reiterates the classification of causes of disease given in his Bradshaw lecture delivered in 1917, as follows: 1. Injury. 2. Food and feeding. 3. Poisons. 4. Occupation. 5. Stress. 6. Abnormal metabolism. 7. Abnormal age-changes. 8. Neoplasms. 9. Parasites, including microorganisms. 10. Heredity. In the present contribution he uses this classification to study the causes of nervous diseases, to estimate roughly their frequency in a busy industrial area, and to emphasize special points as they arise. The writer confesses to finding much difficulty in allotting to each causation group its proper value as a causative factor, partly owing to the fact that there are no tables of morbidity to which to refer, and partly because his classification is not truly logical as the groups are not watertight compartments. For instance, cerebral arteriosclerosis is partly due to abnormal old age and partly due to stress; some occupation diseases are due to stress and some to poisons and so on. But trying to look from a large viewpoint at such nervous disease as he has seen, he would place heredity as the chief cause of nervous disease, including, of course, insanity, which to his mind is just as much a nervous disease as is epilepsy or locomotor ataxia. Then would come abnormal old-age changes and stress, and about this level, injuries. The remaining classes he could not value accurately. Food would be low in the list, as would also

be poisons, but either of these classes would be raised according to whether one included alcohol as a food or as a poison. Neoplasms are rare, especially tumors of the cord, but those of the brain commoner than he used to suppose. Metabolism and occupation pure and simple are probably lowest in the list.

4. Some Remarks on Food Values in Tuberculosis.—Woodcock and Ruston summarize their observations as follows: (1) Tuberculous patients require more food than the average amount needed by the ordinary laborer outside. The minimum for patients in Gateforth Sanatorium (where careful records were kept) contains 3,500 calories, the patients being almost invariably adults. (2) The diet must be rich in protein and fat—protein, 4 to 4½ oz. per head per day; fat, 4 oz. per head per day. The fat should be largely animal fat, particularly in the form of milk and milk products. If margarine is used it should be as oleo-margarine and not made from vegetable fats. (3) Eggs should be in the dietary, and when they are not supplied their place should be taken by an extra amount of meat given according to accurate calculation. (4) Whole-meal bread, beans, peas, and lentils should always be used, together with a plentiful supply of fresh fruits and vegetables grown in the sanatorium grounds. (5) Two pints of milk per day is the amount suggested for each patient. Raw-meat feeding has not been carried out at Gateforth, although it is sometimes prescribed in the sister institution at Armley. Again, in the very few cases of hemoptysis met with at Gateforth, diet has been reduced to the traditional drastic minimum of hospital practice, the sufferers being transferred as soon as possible to a more suitable institution.

2. The Defensive Value of Normal Mucus Formation, and the Theory of Catarrh.—F. G. Crookshank states that the normal function of mucus must be regarded as physiological and purposive. What is its purpose, and what are the consequences of failure in its due performance? It seems pretty clear that a layer of mucoid matter must, in the first place, protect the delicately vascular underlying membrane from the direct action of atmospheric changes—changes in temperature, humidity, composition, and the like—as well as from the no less direct action—mechanical or chemical—of solids and liquids in contact with it. It has been suggested by Benians that the mucoid layer may not only prevent the absorption and inhibit the action of bacterial ferments and toxins by and on the mucous membrane, but may actually prevent invasion of the body by the organisms themselves. If this hypothesis be well founded, the maintenance of a proper state of mucus formation becomes of great importance; and interference with such a proper state constitutes an etiological factor that cannot be neglected when discussing the origins of certain forms of ill health. The customary view is that interference with mucus production is a result of bacterial or protozoal attack; Benians suggested that when from one or another cause—whether vasomotor, hormonic, or nervous—mucus production is seriously disturbed, not only may mechanical, chemical, and other agents do harm, but scope may be given to the activities of organisms which are habitual, occasional, or accidental denizens of the "mucoid layer." There are not a few clinical facts which seem to Crookshank to support this view. The protective effect of mucus in the intestines and in the genital organs of both men and women is important. It is, however, perhaps the state of the respiratory mucous membranes that is, in most respects, of greatest interest. In the light of the hypothesis of the protective importance of the mucoid layer, the rationale of some old-fashioned clinical methods seems clear. He refers to the use of demulcents and of mucilaginous preparations generally, in the acute stages of a catarrh; to the administration, first of medication directed towards the loosening and later towards the diminution, of mucoid secretion; and to the care necessary to avoid premature inhibition, by opiates, of its secretion and removal.

1. Differential Diagnosis of Tuberculosis and Hyperthyroidism.—R. McBrayer, in this preliminary report on a study of the Goetsch test, first reviews this adrenalin hypersensitiveness test and gives the technique thereof. He then takes the following list of symptoms and signs of hyperthyroidism and classifies the findings in each case under the following headings: systolic blood pressure, diastolic blood pressure, pulse rate and quality, tremor, nervousness, palpitation, diuresis, temperature, respiration, pupillary changes, apprehension, vasomotor changes in face, hands and feet, and sugar in the urine. From this study the following conclusions are drawn: If future studies substantiate the findings given, the differential diagnosis of tuberculosis and hyperthyroidism will be made easier for the general practitioner when, after the subcutaneous injection of adrenalin, he finds, between fifteen minutes and one hour and thirty minutes after the injection, the following: 1. A systolic blood pressure rising ten or more points and remaining above normal for fifty-five minutes or more. 2. Increased pulse rate of ten or more points per minute proportionate to the systolic rise. 3. An increase of pulse pressure of thirty-five or more points. 4. Pulse irregular and varying in volume. 5. An increase in respiratory rate of four or more points per minute. 6. Varying pupillary changes.

Hypersecretion of Cerumen in Paralysis of the Cervical Sympathetic.—Cornil found that a number of wounded who presented unilateral symptoms of paralysis of the cervical sympathetic, due to injury of the nerve, complained of loss of hearing on the affected side. Examination revealed in each case a large plug of cerumen in the ear of the side involved, the other ear not presenting evidence of this hypersecretion.—*Gazette des Hôpitaux.*

Book Reviews.

HANDBOOK DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. Herausgegeben von DR. L. KATZ, Spezialarzt für Ohren-, Nasen- und Halskrankheiten in Ludwigshafen a Rh., und PROF. DR. F. BLUMENFELD, Arzt für Nasen-, Hals- und Lungenkrankheiten in Wiesbaden. II Band, Lieferung 4, Preis: M. 14.40; Lieferung 5, Preis: M. 25. Leipzig und Würzburg: Verlag von Curt Kabitzsch, 1919, 1920.

AFTER an interruption of four years the publication of this work has been resumed and with the appearance of the present two numbers is nearing completion. Part 4 comprises an article by Preysing on acute suppurative otitis and paracentesis of the drum membrane, including a series of fine colored plates particularly those illustrating the appearances of the tympanic membrane in middle-ear disease. Part 5 includes an article by Jurasz on the surgery of the faucial tonsils exclusive of tonsillectomy, one by Henke on tonsillectomy, and one by Imhofer on the surgery of the pharyngeal tonsil, all of which articles are accompanied by a series of colored plates. Both of the present numbers maintain the pre-war standard of this work in the comprehensive handling of its subject-matter and in its artistic features.

LEHRBUCH DER VOLKSERNAHRUNG. By Prof. Dr. C. VON PIRQUET and Dr. E. MAYERHOFER in conjunction with Drs. J. HEUSSLER, E. MAYERHOFER, Frau R. MIARI, E. NOBEL, Fr. OBERLEITNER, R. SCHNEEWEIS, and R. WAGNER, Vienna. With 32 illustrations. Vienna and Berlin, 1920: Urban & Schwarzenberg, 1920.

DURING the war Von Pirquet elaborated a new method of calculating the relative value of various food elements based on a standard which is milk. He regards milk as the standard food and compares the relative values of sugar, fat, butter, bread, flour, and other food products by comparison with milk. He designates this as the "Nem" System (*Nutritionis Elementum Milch.*) In figuring the food value he says 1 gram of milk equals 1 nem, 1 gram of sugar equals 6 nem; therefore 180 grams of milk equals 30 nem of sugar. One gram of butter equals 12 nem; 1 gram of flour equals 5 nem; 1 gram of pork equals 10 nem; 1 gram of black bread equals 3 nem. Another interesting point in the method adopted by Pirquet is that he estimates the daily requirement of food according to the height of the body taken in a sitting posture, from the buttocks to the head. A similar method of calculating the food requirement was advised by Voit and Rubner. This new system has many adherents and was the subject of discussion at a recent meeting of the Berlin Medical Society in which a large number of Pediatrists participated. While some opposition was encountered the majority of the speakers seemed to favor the practicability and utility of this system.

THE MECHANISM AND GRAPHIC REGISTRATION OF THE HEART BEAT. By THOMAS LEWIS, M.D., F.R.S., F.R.C.P., D.Sc., Honorary Consulting Physician, Ministry of Pensions; Late Consulting Physician in Diseases of the Heart (Eastern Command); Physician to the Staff of the Royal Medical Research Committee; Physician and Lecturer in Cardiac Pathology, University College Hospital, London; Fellow of University College, London. New York: Paul B. Hoeber, 1920.

THIS is the most important work so far published dealing with the new science of electrocardiography. It is really a new edition, though greatly amplified, of the author's work on "The Mechanism of the Heart Beat," and contains an account of all the knowledge of this intricate subject that has been acquired during the interval since the appearance of that work eight years ago. The following are the titles of the chapters which will give the reader an idea of the completeness with which the subject is covered: Special anatomy; Mechanical records of the heart beat with especial reference to intra-auricular pressure curves and venous records; Galvanometric method; The broad features and time-relations of the normal electrocardiogram and certain principles of interpretation; The normal pacemaker of the mammalian heart; Function of the *A-V* bundle and curves resulting from lesion of its two divisions; Spread of the excitation wave in auricle and ventricle; The meaning of certain ventricular deflections; Aberrant contractions and the electrocardiograms of hypertrophy, etc.; The analysis of disordered mechanism: (*a*) arterial pulse curves, (*b*) venous curves, (*c*) electrocardiographic curves; Experimental heart block; Clinical heart block; New rhythm centers; (*a*) atrioventricular rhythm, (*b*) idioventricular rhythm, etc.; Ventricular extrasystoles; Auricular extrasystoles; Premature beats arising in the junctival tissues, retrograde beats; premature beats disturbing new rhythms, etc.; Paroxysmal tachycardia of supraventricular origin; Paroxysmal tachycardia in which the ventricular systoles are abnormal; Auricular flutter; Auricular fibrillation; Ventricular fibrillation; The heterogenetic impulse and the interrelation of extrasystole, paroxysmal tachycardia, and fibrillation; Observations upon the nature of paroxysmal tachycardia, flutter, and fibrillation; Causes determining extrasystoles and allied disorders; Sino-auricula block, so-called; Cardiac syncope and unexpected death; The vagus; Alternation; Bibliography and author index, the latter containing 801 titles. There is also a glossary of terms as used in the book.

HEART TROUBLES: THEIR PREVENTION AND RELIEF. By Louis Faugères Bishop, M.A., M.D., Sc.D., F.A.C.P. Professor of the Heart and Circulatory Diseases, Fordham University, School of Medicine, New York City; President of the Good Samaritan Dispensary; Physician to the Lincoln Hospital; Chairman of the Section of Historical Medicine of the New York Academy of Medicine; Member of the American Medical Association, of the Medical Veterans of the World War, of the American Therapeutic Society, of the New York Pathological Society, of the Society for the Prevention and Relief of Heart Disease, and of the Alumni Association, St. Luke's Hospital; author of Arteriosclerosis and Heart Disease and Blood Pressure. With illustrations. New York and London: Funk and Wagnalls Company, 1920.

PROCEEDING upon the premise that the time has passed when much that pertains to the nature of a sick person's illness can be concealed from him, the author of this interesting and valuable addition to the literature of modern cardiology addresses those who are suffering from heart troubles or are interested in the subject, and also "those who are willing to dispense with all disguise and to see things as they really are." Those who prefer not to know that their hearts are disordered when they are, and who would rather be told that the whole trouble is "indigestion," "nervousness," or something else, are not the ones to be benefited by Dr. Bishop's book. The family or immediate relatives of those who suffer from heart disease, especially nurses in attendance upon these patients, may well give careful heed to the suggestions contained therein. The intelligent layman, whether a "cardiac" or not, will find in this volume much that is interesting and instructive, and the physician who has not specialized in the study of cardiovascular disease may discover in it refreshing reminders of much that he is in danger of forgetting. Part I, which deals with matters of physiological and symptomatic import, contains chapters on consciousness of the action of the heart; the heart as an engine; the circulation of the blood; the pulse; disturbances of the circulation; what is meant by hardening of the arteries; causes and symptoms of heart disease; the passage of the blood through the heart; the irregular heart; the nature of the disorder of the heart beat; the examination of the heart patient. Part II, which deals with therapeutic matters, contains chapters relating to foxglove or digitalis; nitroglycerin and how to use it; heart troubles and the cure resort; blood-letting in heart disease; how to meet emergencies; the care of the heart; the animal proteins; reconstruction in heart disease; the heart and the kidneys; health—how remedies should be given to keep it; tea, coffee, and tobacco; the danger of the heart from antifat treatment; the care of the heart during pregnancy; nursing in heart troubles.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held October 1, 1920.

Dr. SEWARD ERDMAN in the Chair.

Filaria with Hydrocele (Two Cases).—Dr. CHARLES EVERETT FARR presented these cases. He stated that both of these patients had been citizens of South or Central America, one having been born there and the other having lived there for some years. The condition was one with which we were not familiar in the United States, but with the rapid growth of business relations with the South American countries filaria was being met with more frequently. During the past year he had met with five cases, in four of which filaria was diagnosed in the course of operative treatment for something else. The first patient, a young man, presented himself because of a femoral hernia and a large mass of femoral nodes. It was thought that possibly the condition was a lymphangioma. On examination of a section of these nodes an adult worm was discovered. This was a very unusual finding, as it was an extremely rare occurrence to find a worm in an external node. The patient gave a history of having had occasional attacks of fever and chills which laid him up for a few days or weeks, and he had an enlargement of the nodes in the femoral region and an abscess on the thigh. After the operation the wounds healed up and he made an apparently perfect recovery. He also had a small hydrocele which was presumably of filarial origin. Shortly after his discharge from the hospital the patient noticed a swelling on his thigh and he was found to have a high fever and leucocyte count. He was then kept in the hospital for a few weeks, during which time he passed through a crisis but finally recovered, and at present was in excellent health. The second patient had a large hydrocele and a small mass of nodes. The speaker operated on the hydrocele and took the nodes for diagnostic purposes, but was not lucky enough to find an adult worm, nor could they have expected this in view of the rarity of such a finding. The patient made a good recovery, though there was some thickening of one side of the scrotum and enlarged nodes. They knew and he knew himself that he harbored the filaria organism, and might have other attacks but at present he had no symptoms. In speaking of the treatment of relief, Dr. Farr stated that surgical procedures were merely for the relief of symptoms, and that no treatment had yet been found successful in eliminating the parasite. Salvarsan had given relief in some instances but it was a question whether it killed the worms. Usually symptoms were caused by the adult worm blocking a blood vessel and causing a thrombosis and on this a mild streptococcus infection was frequently imposed. In one of the cases presented they had found a streptococcus infection at one time, but the actual progress of the lesions was obscure. He had been given the impression that usually there were only one or two adult worms in the body and if one could eliminate them the patient would be cured.

Dr. EDWARD WALLACE LEE said he regretted that he had not arrived in time to hear all that Dr. Farr said about filaria and hydrocele. During his war experiences in Porto Rico he had seen a great many hydrocele patients in whom the hydrocele was accompanied by elephantiasis of the scrotum which was said to be due to filaria. He had operated on a number of these hydroceles and there was very little bleeding but a milky exudate resulting from the disease, which was so abundant that you could easily see it. To the real pathology or bacteriology of these conditions Dr. Lee said he had not paid much attention but in Porto Rico the hydrocele and elephantiasis were attributed to the filaria.

Dr. SEWARD ERDMAN asked Dr. Farr if he could not tell them more of the life history of the filaria. It would be interesting to know this in view of the fact that they were likely to see more of these cases as our business relations with South America increased. He would like to have Dr. Farr tell them why he supposed there were only one or two adult parasites in the body.

Dr. FARR said filaria was said to be somewhat like malaria in that it went through a cycle in the host, but the worms did not go on to reproduction in the host. It used to be thought that infection occurred through drinking water, and that the embryo burrowed through the bowel and multiplied, but that always there would be only one or two worms.

Dr. EDWARD WALLACE LEE said that in Porto Rico the infection was supposed to be due to the mosquito. The embryo parasites are said to be found in the peripheral vessels only at night, but not during the day. He had tried to demonstrate them at night but had not succeeded.

Ostitis Cystica Fibrosa of the Ulna.—Dr. CHARLES EVERETT FARR presented this patient, a woman 32 years of age, who had had perfect health until May of this year, when she fell and sustained a number of fractures, one of the humerus, one of the ulna and one of the os calcis. The ulna and radius, as shown by the roetgenograms, were thickened and a curious condition was present which they had disagnosed as ostitis cystica fibrosa. The Wassermann was negative, but the patient was given mixed treatment. Opinions of men experienced in bone surgery were that the condition was tuberculous or ostitis cystica fibrosa. The patient was operated on and a growth found in the upper end of the ulna, not quite like ostitis cystica fibrosa. The pathological examination, however, showed this condition to be present. A graft from the tibia was fitted in but the lower end was not yet firm, making manipulation unsafe at the present time. The lower end of the graft was not inlaid as it broke while being put in, and it was not deemed wise to prolong the operation. It was deemed wise to remove the growth as it might go on to malignant disease. Ostitis cystica fibrosa had been assigned to various causes but nobody seemed to know the exact etiology.

Dr. WALTER M. BRICKNER asked whether roentgenograms had been made of the other bones of the body, and especially of the bones that had been fractured. The *x*-ray picture indicated that there was also disease of the humerus and of the entire shaft of the ulna, and it was well known that ostitis cystica fibrosa was often a multiple bone involvement.

Dr. FRED H. ALBEE mentioned that he had seen quite a number of such cases and that they came to the surgeon largely because of fractures through the involved area. In his experience he had seen a number of cases in which this condition was limited to one bone and were not multiple. It would have been better in this case if the upper portion of the graft had been inlaid, for where a graft was put into a marrow cavity one was not so likely to get union. Dr. Albee stated that he had obtained good results in several instances where he had inlaid strong grafts right through the tumor without the removal of the shaft of the bone.

Dr. ERDMAN asked whether the trauma was sufficient to account for the condition.

Dr. FARR replied that the trauma was very severe, though the fractures were of the ordinary type. Roentgenograms had been made of other bones which showed nothing except the condition at the lower end of the humerus which they had all observed. There was complete degeneration of the ulna, but at the time of the operation the disease was not apparent in the humerus. In reply to Dr. Albee's remark about the advantage of an inlay instead of an intramedullary contact, in describing the case he had mentioned that he had been unfortunate in breaking the graft and it had not seemed wise to prolong the operation further.

Mouth Diagnosis from a Dentist's Viewpoint.—Dr. H. J. KAUFFER made this presentation which was illustrated by lantern slides and moulages. He expressed the hope that he would make his hearers feel as he did—that the dentist should recognize pathology which came within the radius of his observation. The dentist's practice was limited to the care of the teeth for which he had accustomed his patients to present themselves once a year. His object this evening, he stated, was to show that the wide-awake dentist would frequently find conditions requiring medical and surgical attention, and by doing so the treatment of these conditions would often be started before the patient was conscious of disease. In regard to focal infection this was the same in the mouth as elsewhere in the body,

unless it responded favorably to the treatment it must be removed. There was a becoming tendency in dentistry to place reliance on the comparative blood count and streptococci complement fixation test in determining the patient's resistance to apical abscesses. In his experience these were of relatively negative value, due to the fact that in periapical abscesses, the organisms are encapsulated and do not produce a leucocytosis. He found that most information could be gained by making a mouth examination in a dark room, using direct illumination for the external examination of the mucous membranes and teeth, and transillumination for the teeth. It was well known that a small contracted tonsil was frequently more infected than a large tonsil, and when the dentist observed this pathology, he should refer the patient to the rhinolaryngologist. Any tissue enlargement in the mouth or throat which was persistent should be regarded with apprehension unless one was positive that it was benign. The decision in this respect, however, he did not believe belonged to the dentist. The case should be referred to the surgeon for diagnosis. As regarded the examination of the teeth by transillumination, any opacity in infected teeth was caused by the disintegration of organic tissue, so that an infected pulpless tooth gave a blue-gray color under transillumination. The maxillary sinuses should also be transilluminated, and if they did not transilluminate clearly the patient should be referred to a nose and throat specialist. To test the vitality of a tooth, from one to forty volts with five milliamperes of electricity might be used upon the teeth. But since individuals varied greatly as to their tolerance of electricity, the negative pole should first be applied to the patient's lips to determine his tolerance. Occasionally the patient would tolerate a very high voltage of electricity. Tabetics had been found not to respond to 30 or 40 volts. When a patient was found whose tolerance to electricity was high he should be referred to the neurologist and some pathology might be found by a man familiar with that work. Dr. Kauffer described the technique of testing for devitalized teeth, illustrating it by lantern slides and exhibited a chart which enabled one to tabulate all the findings in such a way that they would be evident at a glance. In the detection of infected and devitalized teeth the *x*-ray not always an infallible guide. Exostosis of the roots of teeth not accounted for by trauma such as produced by irritation due to an ill-fitting cap or malapposed tooth were due to systemic disturbance. In examining 100 luetics 31 were found to have exostosis of tooth roots. Among 1000 patients without a blood history of the case, the *x*-ray showed only 5 per cent. of exostosis of the tooth roots. Of the 100 known luetics examined a budding of the periosteum in 29 cases was observed, which phenomenon, he stated, had been reported by other investigators. Where there was relative radio-density of the exostosis, radio-density was usually found in the bone tissues of the hand and a radio-lucent exostosis usually accompanied radio-lucent bone tissues of the hand. Slides of cases of acne vulgaris were shown in which the same organism was isolated from the apical abscesses and skin lesions, though this finding was by no means uniform in all cases. A series of slides were then shown, illustrating such lesions as—chancre, recurrent luetic sores, erythemas, geographical tongue, lichen planus, epithelioma and a case of angioneurotic edema as a result of reflex nerve disturbance caused by an impacted tooth. All such conditions the dentist should recognize and refer to the appropriate specialist for treatment.

Dr. KAUFFER, in reply to the question as to whether he had observed instances in which a positive Wassermann had become negative following the elimination of mouth infection, said he had not observed this—but had noticed the opposite. It was known that toxins influenced the Wassermann reaction. It had been his experience that when a luetic's infected teeth were cleared up and infection eliminated a negative Wassermann reaction became positive, but he could recall no instance in which a positive Wassermann had become negative after the removal of infected teeth, although he could understand how the rapid absorption of toxins, which always follows the extraction of infected teeth, might temporarily influence a Wassermann reaction and be responsible for the negative findings of which the doctor spoke.

Certain Fundamentals in the Treatment of Shoulder and Hip.—Dr. FRED. H. ALBEE made this presentation, which consisted in a lantern slide and motion picture demonstration. He described certain features of the fracture-orthopedic table which he had devised to meet the fundamental mechanical principles involved in the treatment of certain hip and shoulder conditions which were not met by other apparatus. The speaker emphasized the importance of such an apparatus which allowed the accurate control of both upper and lower extremities, both as to desired amount of traction and posture in all fractures and orthopedic conditions. It was an indispensable part of the surgeon's armamentarium in the treatment of all such conditions. This table provided for the control of both upper and lower extremities as no other table did. The upper end of the traction arm was adjusted by merely turning a crank, and could be adjusted in each individual case, so that it came immediately beneath the hip joint or to the inner or outeer side of it as was indicated. This was a distinct advantage, as it was extremely important in many types of cases, as, for instance, in comminuted fracture of the floor of the acetabulum with displacement into the pelvis, that traction should not only be maintained, but increased during the reduction of the dislocated hip by swinging the limb into a posture of physiological abduction. No other apparatus provided for the constant maintenance of traction while the limb was changed from adduction to abduction except the Bradford apparatus for reduction of congenital dislocation of the hip, which could not be adjusted to any fine degree. In the case of the fracture of the floor of the acetabulum, the modus operandi of reduction when the table was used was as follows: The posture of abduction brings the tip of the great trochanter as a fulcrum against the side of the pelvis just above the rim of the acetabulum, and when this abduction was forcibly increased to physiological limits or more, the femoral head with a portion of the bone fragments of the floor of the acetabulum was levered out of the pelvis. This reduction was much enhanced if the traction on the limb increased as the limb was forced out into increased abduction. This was brought about by adjusting so that the upper end of the traction arm was outside of the center of the hip joint. In the application of Whitman's abduction treatment of fracture of the neck of the femur by plaster spica, this fracture table had been found to be of the greatest service as also in the postoperative fixation following a bone peg-graft operation for non-union of the neck of the femur. In this instance it was also very important that a change in the degree of abduction during the operation should not destroy the table traction. In cases of ankylosed hip with abduction deformity, one did a circular osteotomy and then swung the lower fragment of the femur out on its upper fragment and the pelvis, and fixed it at an obtuse angle with the lateral axis of the pelvis, and in this way the leg could be made practically two or three inches longer. When using the speaker's table in this procedure, the danger of lower fragment sliding by the upper fragment was much lessened by the maintenance of full traction throughout. In tuberculosis arthritis, or where there was luxation of the head of the femur upward from a disintegrating arthritis, it was desirable to maintain constant traction, as the limb was swung outward into abduction during the process of reduction, or it might be advantageous to increase the traction; this apparatus permitted of perfect control of the degree of traction, so that it could be increased or diminished as the limb was swung into abduction or adduction, whereas with all other apparatus it was impossible to make any such adjustment whatsoever. Dr. Albee stated he had always emphasized the importance of posture in the treatment of all juxta joint fractures. Posture was most important in the treatment of epiphyseal separation of the hip, such as occurred in obese adolescent patients either from slight trauma or sometimes without any trauma whatever. In such cases one never needed an internal fixation agent; all that was necessary was to get the parts in position and keep them there by the posture of the limb and the pelvis. In fresh fracture of this type the ideal method

of reduction and fixation was to pull the lower fragment down by traction table traction until the limbs were of equal length, and then strongly rotate the limb internally until the toes pointed upward which brought the fractured surfaces in contact with each other. The next step, and a most important one, was to abduct the limb to the physiological limit while the traction on the limb remained constant. This brought the point of fracture (the fragments of which had been completely reduced) into the acetabulum, the roof of which acted as an internal splint and absolutely prevented redisplacement as long as this posture of inward rotation and abduction was maintained. A long plaster of paris spica served as an ideal retention splint. In old cases of this type where mal-union had taken place, an open operation was indicated, for the purpose of separating the mal-union by osteotome. The method of reduction and fixation was then precisely the same as described above for freshly fractured cases.

In old cases of fracture of the neck of the femur when the capital fragment had become much shortened by erosion, the speaker has employed for several years the following operation: Through the Sprengel or Smith-Peterson approach to the hip joint the head of the femur was removed. The tip of the trochanter and a strip of the cortex on the outer aspect trochanter and shaft of the femur about three inches long was removed *en masse* with attached short abductor muscles. The stump of the neck of the femur and the top of the trochanter were then rounded and by swinging the limb into strong abduction were then inserted into the acetabulum. The parts were held in this position by the posture of extreme abduction and careful moulding of the plaster. The result was a stable, painless hip with a good amount of motion. The advantage of such a fracture table in this procedure was apparent. The position of abduction held the trochanter fragment at an acute angle with the femoral shaft while union took place, thus forming a lever by which the attached abductors were able to restore to a varying degree the function of abduction. Dr. Albee then demonstrated the management of injuries of the upper extremity, especially those involving the complete loss of the head and portion of the shaft of the humerus and soft parts about the shoulder joint. These injuries he considered under two headings, those in which both masculature and upper end of humerus were absent to such a degree that the possibility of restoring shoulder joint motion was *nil*, and the object was to ankylose the joint by the same tibial grafts which restored the less of the humeral bone with the arm in a posture of anterior elevation, and those in which the musculature has been so far preserved that shoulder joint mobility might be restored, in which case the upper end of the humeral shaft and head are restored by using the upper portion of the fibula. The case of a pianist was reported where 5 inches of the humerus, including the head, was lost as the result of comminuted fracture. The function was so far restored by transplanting about 6½ inches of the upper end of the fibula that the patient was able to resume her profession and was at the present time not only giving piano lessons, but appearing in concerts before the public. The posture of anterior elevation of the upper arm with rotation upward so the hand came in front of the chin gave the best function in ankylosis of the shoulder whether from operation or disease, as in this posture of humerus to the scapula the scapular thoracic motion compensates for loss of motion at the shoulder joint. Among the motion picture films was one showing the method of dealing with a case in which four inches of the humerus was missing resulting in a flail joint. A ten-inch incision was made dissecting out all scar tissue and preserving the musculospiral nerve. A graft eight and one-half inches long was then taken from the tibia and inserted into the humerus. *X*-rays taken at intervals up to six months were shown, demonstrating almost a complete restoration of diameters of humeral shaft. Almost complete restoration of shoulder and arm function was also shown in the moving picture. In bone grafting Dr. Albee stated that he found bone slivers with marrow on one side and periosteum on the other of more value in promoting osteogenesis than merely small bone fragments or the osteo-periosteal graft. He emphasized the value of the motion picture as an aid in teaching surgical technique, particularly to undergraduate students.

Dr. W. M. SILLECK questioned whether the position in which Dr. Albee placed the arm did not abduct it too much. He said Sir Robert Jones advocated the anterior elevated position but abducted the arm to such an extent that the patient could bring his hand to his mouth or head. He though this position was better than that in which the arm was in practically complete abduction.

Dr. Albee, in closing, stated he had especially endeavored to give Dr. Whitman due credit for what he had taught in regard to the abduction treatment of fracture of the hip. In reference to the implantation of the trochanter into the acetabulum after the removal of the femoral head following old fracture of the neck with extreme erosion of the capital fragment, Dr. Albee stated that he had published this operation several years ago in the Journal of Orthopedic Surgery and that he had secured many very satisfactory results. As to ankylosing the upper arm, whether by grafts in restoring loss of bone at upper end of humerus or by a plastic operation on the shoulder joint, in a posture of anterior-elevation to the trunk, or in the laterally abducted position, the speaker said he had had an exceptional opportunity to observe the relative merits of the two and found that the anterior-elevated posture was the one which gave a much more efficient arm. This was especially true since the most difficult things for a patient with a stiff shoulder to do were the bringing of the hand to the hair, the neck tie, and to the face for the purpose of feeding himself, and other similar functions. It was remarkable how well the arm functionated in this posture.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 8, 1920.

DR. CHARLES HENDEE SMITH IN THE CHAIR.

The Psychology of the Cardiac and the Doctor.—Dr. ROBERT HURTIN HALSEY presented this communication, in which he stated that children with heart disease had varying degrees of specific deviation from the normal, and frequently certain general, acquired mental, social, educational, and environmental differences. They frequently showed a lack of initiative, a disinclination to associate with others; often a moderate grade of school knowledge, and a certain eager readiness to attribute their backwardness and inefficiency to heart disease. It seemed that these general deviations were derived from three sources, namely, the family, friends and teachers, others with heart disease, and the family physician. There was a popular tradition that "heart disease" connoted the possibility of sudden death. Unfortunately popular tradition made and knew no distinction in degrees or forms of the disease. The doctor was frequently responsible for unnecessary medicine and undue restrictions because the patient was not thoroughly studied, and his limitations determined, but rather all cardiacs were treated as hopeless cases with the expectation of imminent early death. Since primarily the physician must instruct family, teachers, and cardiac, it seemed to the writer that the means of modifying these various mental influences which increased the introspection of the cardiac, increased his hopelessness and retarded his physical and mental development, were worthy of their attention. The child could and would adjust itself to restrictions if it had some substitute method of occupying its physical energies as well as satisfying its mental desires. The cardiac child reacted to environment and was stimulated by group work to rapid development, mentally and physically. A wholesome mental atmosphere was created by encouraging active, useful recreation work, and the pursuit of some vocational training suitable to the creed, race, and social status of the child. The physician could obtain better results and perform a greater service by a more careful study of the individual cardiac and the social problems involved. Physical exercises properly directed in games, dancing, and occupations would help to improve the cardiac muscle and the mental attitude or temperament of the child. Gathering cardiac children in groups did not produce

hypochondriac depression, but rather stimulated a rational cheerfulness. The individuals learned to discriminate and differentiate between the severity of their conditions. The individual improvements were noted, and the whole group derived encouragement. Where there was better understanding of the restrictions, there was better co-operation, and better co-operation meant better results in a longer and more productive life.

Syphilis in Children of School Age with Heart Disease.—Dr. BLAKE F. DONALDSON presented this paper by invitation. He stated that during the last school year, 28,000 children were on the register in a district of seventeen schools, located in New York's lower East Side, assigned to the Cardiac Clinic of the Post Graduate Hospital. All the new children in these schools, together with such of the other children as were suspected of having diseases of any kind, were examined by school medical inspectors of the Department of Health. Seven hundred children were thought worthy of note because of some cardiac abnormality. These selected cases were then passed upon by Dr. Robert Halsey and a staff of assistants. Of these cases 167 were found to have organic heart disease—forceful sounds, reduplications, high pulse rates, and accidental murmurs accounting for the rest. The Department of Health of New York City reported that the incidence of heart disease among school children, as noted by its medical inspection, in 1918 was 1.6 per cent. In their group of 167 organic cases, there were 13 cases of organic insufficiency, and five of pulmonic insufficiency, in combination with either mitral stenosis or mitral insufficiency. Of these children, 84 were selected for medical observation in a special class connected with Public School No. 64. The work was in the nature of an experiment to determine the wisdom of segregating school children with heart disease. The comparatively large number of aortic cases (8 per cent.) in their series was rather a surprise. In the aortic cases the diastolic murmurs were best made out with the patients in the erect position after forced expiration. One hundred and three Wassermann reactions were made on the 84 children registered and on the mothers and other available relatives of the children with aortic insufficiency. A positive Wassermann was obtained in only one child. This was a well compensated case of aortic insufficiency with a history of frequent attacks of tonsillitis and one severe attack of acute rheumatic fever. The mother's reaction was four plus. Neither the mother nor the child showed any other evidence of syphilis. One case of potential heart disease was of special interest. This was a child with a marked anemia of the pernicious type, with a high color index and many nucleated red cells, a marked enlargement of the spleen and liver and slight generalized icterus. Out of a family of eleven people eight members were affected in almost the same manner. They all had the primary type of anemia with splenic enlargement. The aortic cases noted all had definite histories of acute rheumatic fever, save one who had only had diphtheria. In children one expected to find aortic disease as the consequence of rheumatism, syphilis, or some extraordinary strain. Of late years, perhaps because of improved diagnostic methods, syphilis as a causative factor, especially in children had been over-emphasized. Abbott stated that by far the chief cause of aortic disease in persons under middle age was rheumatic fever. Statistics were quoted from a report of Poynton, Aggazzis and Taylor on 250 autopsies on children who died of rheumatism showing the different types of cardiac involvement found. It might be concluded from this limited number of cases that syphilis was not a very great factor in the causation of heart disease in children.

Circulatory Reactions to Test Exercises in Children with Heart Disease.—Dr. MAY G. WILSON made this presentation, which was a preliminary report having for its objects: (1) To increase the number of observations of a previous study on the circulatory reactions after test exercises in normal children; (2) to compare the circulatory reactions after test exercises in the cardiac group with those obtained in the normal group; and (3) to study the exercise tolerance of children with heart disease to standard test exercises. These investigations were conducted upon a group of average normal girls ten to fifteen years of age, and upon a group of 65 children with cardiac disturbances, including all manifestations of organic heart lesions, congenital and acquired, as well as possible and potential heart disease. The test exercises used were: (1) Swinging one or two iron dumb-bells (2-3-4-5-7 and 10 pounds each); (2) stairclimbing tests, two and four flights (20 to 60 steps) a rise of fifteen and thirty feet, taken in 20 to 30 seconds; (3) jumping rop 100 times in 100 seconds; (4) setting-up exercises, thirty minute drill daily for six weeks. The circulatory reactions following these test exercises in the group of normal girls, and in the cardiac group confirmed the results obtained in the earlier investigation. The circulatory reactions following the stair-case test and the rope-jumping test were similar to those obtained in the dumb-bell test. A working table was formulated of standard test exercises followed by normal systolic blood pressure curves, without symptoms of dyspnea and fatigue. It was standardized from an analysis of reactions of an average group of 35 normal children, according to age, weight, and height. The degree of distress and type of systolic blood pressure curve following standard test exercises was used as a gauge in estimating the exercise tolerance of children with heart disease. Of the 40 children having definite organic heart disease, without symptoms of insufficiency, approximately two-thirds had a normal tolerance for standard test exercises, and one-third had a fair tolerance. An analysis of the case histories of the cardiac group showed that in 90 per cent. the children were excused from school exercises; in 75 per cent. free play had been interdicted by either physician or parent, but nevertheless 61 per cent. admitted ability to tolerate stairs and games equally well with playmates. Five illustrative cases were cited.

The Place of Tonsillectomy in the Management of Cardiac Disease in Children.—Dr. WILLIAM ST. LAWRENCE made this contribution, which consisted in an analysis of a series of 85 children, each of whom had present one or several of the rheumatic manifestations before the tonsils were completely removed and all of whom were observed during an average period of three and one-half years after the operation was performed. The tonsils were markedly hypertrophied in 13 per cent. of the cases, and not enlarged in 18 per cent. of the cases. They were the site of recurrent inflammation before the tonsils were removed in 73 per cent. of the cases. "Sore throat" recurred after removal of the tonsils in 7 per cent. of these. At least two operations were necessary before the tonsils were completely removed in at least 22 per cent. of the cases. The tonsillar lymph nodes were enlarged in 100 per cent. of the cases before the operation was performed, while in 59 per cent. of the cases they were impalpable afterward. One or more attacks of acute rheumatic fever had occurred in 42 cases before the tonsils were removed. After tonsillectomy there were no more recurrences in 35 cases, or 84 per cent. One or more attacks of chorea had occurred before the removal of the tonsils in 40 cases, and there were no recurrences of the chorea in 20 of these cases, or 50 per cent. Sixty-one cases showed myositis and bone or joint pains before operation was performed, and there was no recurrence in 47 cases, or 77 per cent. Fifty-eight cases of organic disease of the heart were present in the series. Twelve of these patients had suffered at least one attack of cardiac failure before the tonsils were removed. One patient suffered one attack afterward. The exercise tolerance seemed to be favorably influenced by tonsillectomy in the cases of cardiac disease in the instances in which indications existed for the removal of the tonsils. Nutrition and general health were improved, and intercurrent disease was less frequent after the tonsils were removed. Tonsillectomy (complete removal of the tonsils) would seem to be the most important measure at present available for the prevention of acute rheumatic fever and the allied rheumatic manifestations.

Dr. THEODORE B. BARRINGER, JR., said he thought Dr. Wilson had presented a very important piece of work because it furnished the groundwork for the intelligent treatment of heart disease in children by exercise. Of course, it might be assumed with much reason that children would respond to exercise treatment in the

same way that adults did, yet the actual proof had been lacking until now. The speaker stated that he had been watching Dr. Wilson's work on a number of occasions and was impressed by the careful and conscientious technic she used. As regards her results it was quite interesting to see how rapidly the pulse returned to normal, almost invariably inside of two minutes. This return to normal was of no value in children as a criterion of their exercise tolerance and really of but little value in adults. The effects of exercise upon the blood pressure curve showed the same types as in adults. The term exercise tolerance Dr. Wilson used very frequently. He felt that we should be very clear in our minds as to the significance of that term. The term exercise tolerance simply put before us the conception that the best way of judging of a heart's capacity was by the way the person tolerated exercise. That was a valid conception, because the best way of ascertaining any organ's capability was by setting it doing its own particular work, and basing our judgment on the result of such experiments. Whether a person tolerated exercise depended essentially upon the heart's reserve power, assuming that the lungs and muscles were functioning in a normal way. Dr. Wilson qualified the term by specifying the amount and kind of exercise and that was a very necessary qualification, because the term exercise tolerance might mean very different things. One person might tolerate walking on the level very easily, but would be distinctly overtaxed by climbing stairs. One point brought out was that 90 per cent. of cardiac children did not take exercise in the public schools because it was interdicted. That was a striking commentary on the way these children were being treated. Exercise undoubtedly increased the resistance to general infections in those children exactly as it did in normal children, and also in all probability increased the resistance of the heart itself to reinfections. Dr. Wilson had made a very valuable contribution because she had provided a sound experimental and physiological basis for the treatment of heart disease in childhood by physical exercise.

Dr. L. E. La Fetra said the important lesson to be drawn from the papers was that as physicians we should foster a more cheerful sentiment among the laity with regard to heart disease; we should excise the varicose vein of gloom.

Dr. Henry Heiman, referring to Dr. Halsey's paper, said it was extremely difficult to tell what the future was going to show when a child had his first and primary attack of heart disease, whether this was going to recur or not. He believed they were not in a position to say whether there would be a recurrence. He agreed with Dr. Donaldson that in every aortic cardiac case the Wassermann test should be made, but in very few would a positive Wassermann be found. He also agreed with Dr. Barringer that Dr. Wilson had given them a valuable contribution. She had given a test for the physiological heart and for the pathological heart, so that one could test practically and accurately what a patient could do. It recalled Hertel's work in mountain climbing for adults with heart disease. As to Dr. Lawrence's view in reference to tonsillectomies, that a great many men gave merely opinions on the subject. What we needed was broader clinical observation. He thought they were all agreed that there must be definite indications for the removal of the tonsils. These indications were: (1) Hypertrophy with marked obstruction. (2) Infection. (3) Repeated attacks of tonsillitis. (4) Enlarged adjacent lymphatics. Of course, when the tonsils were removed the child no longer had repeated attacks of tonsillitis, but there might be manifestations of systemic infection. Many of these children previously diagnosed as having tonsillitis, after the tonsils were removed might develop a pharyngitis, a faucitis, or an adenitis, lasting three or four days. This was often diagnosed as a cold. or, if there were symptoms referable to the stomach, as stomach trouble. The systemic disease that would have caused tonsillitis if the tonsils were not removed was still present and might manifest itself in other ways. One should never promise that a tonsillectomy would prevent a cold, and it should be recommended only in cases in which it was definitely indicated.

Dr. Herbert B. Wilcox expressed gratification in that Dr. Halsey had emphasized the importance of the mental reaction of these young patients to the limitations which their infirmity placed upon them, and its possible exaggeration by the attitude of the parents, friends, and particularly the physician, who alone often initiated this attitude, or was in the best condition to control it. There was no important element in determining the degree of effect which the lesion was to produce on the child's life, than the failure of success of those in control to produce in the child a proper attitude toward his physical condition. This important factor had been largely neglected. In regard to the role of the tonsils as a portal of entry, and a seat of elaboration of toxins, Dr. St. Lawrence's experience and belief must be those of all of us. Children who had asthma, those who suffered from chronic digestive disturbance with periodic exacerbations resulting in all the evidences of acute gastrointestinal disturbances with toxemia; those who presented repeated attacks of vomiting without apparent cause; each of these types seemed to divide itself etiologically into two groups, the one depending upon the continued absorption of the products of bacterial activity from a known or unknown source, the other depending upon the constant absorption of toxic material due to the disturbance of the chemistry of digestion. These two causative factors were about equal in importance, and of the former the tonsils were at fault in the majority of cases. Regrowth of the tonsil might occur more or less frequently according to age, and according to the completeness of its enucleation, and if recurring might cause a repetition of the former poisoning. There could be no doubt that the lingual tonsil was quite as important as the faucial tonsils in causing cough as a result of mechanical irritation of the throat, and in increasing the susceptibility of the upper respiratory tract to infection. How much the lingual tonsil was responsible for symptoms due to absorption was less certain. However, it should be considered in each case, and if it was abnormal it should be as carefully removed as the contents of the tonsillar fossa.

Dr. Louis Faugères Bishop said he liked the idea of taking gloom out of heart disease. There was nothing greater came to the man dealing with heart disease than the satisfaction derived from the restoration of confidence. He had seen these children with cardiac disease who were practically invalids after they had learned that they could exercise come back at the end of a year cheerful and bright, doing everything within reason, and in every way different beings, all because somebody used the experimental method and the child was allowed to do everything it could do without objective or subjective discomfort. There was no rule as to the amount of exercise that should be permitted. The old-fashioned method of putting children with cardiac trouble to bed for prolonged periods of time was very foolish. When the period of infection had passed there was certainly no reason for keeping the child in bed. After a certain time the hypertrophy was no greater if the child was allowed to be about than if it was kept quiet. There was another important point in the prognosis and that was with reference to the effect of diet. These children, especially those with aortic involvement, had a strong tendency to develop kidney complications; such complications were much less likely to happen if the child was kept on a lacto-vegetarian diet. The fatal termination was indefinitely postponed in some of the worst cases by strict attention to diet. Also the question of resistance needed emphasis. These children were less likely to have infections if they were kept in good health. However, the doctrine of the experimental determination of the limits of exercise must be applied also to those with failing compensation, and those who did not respond must be duly restricted. They had given the exercise pendulum such a push that it was sure to go too far in unskilled hands.

Dr. Roger H. Dennett said he understood Dr. St. Lawrence to say that he advocated the removal of the tonsils in 90 per cent. of the children with cardiac disease. He did not see why Dr. St. Lawrence did not say 100 per cent. of cardiac cases, in a child with good compensation. It was perfectly obvious that we did not know what was at the bottom of a tonsil by looking at the outside. He said that Dr. Wilcox spoke of many

cases of periodical vomiting and cyclic vomiting, and said that many of these cases were due to the tonsils. He thought that in the list of those conditions in which the tonsils should be removed nephritis should be included, and that the tonsils should be removed in 100 per cent. of nephritis cases. Here was something that could be done in a curative way and in a very definite way, so why not do it every time? With reference to Dr. Wilson's tests, he wondered whether she had ever felt that the tests had ever done any harm, that was in giving the severe tests.

Dr. WILLIAM ROSENSON thought the psychological effect on the patient and the patient's parents could not be emphasized too strongly. We should not make a diagnosis of cardiac disease, as often occurred, from simple auscultation of a cardiac murmur. We so frequently saw cases diagnosed as cardiac disease by school physicians and general practitioners simply because a cardiac murmur was present. He had seen several such cases in which there were loud, rough, blowing murmurs transmitted to the left which were observed for some time and had entirely disappeared. The electrocardiograms, however, were normal, the *x*-ray showed no enlargement, and there was perfectly good function. He had seen also a number of cases, about 10 per cent. among 200 at Mount Sinai Hospital, in which aortic insufficiency was associated with mitral disease, and he did not think that aortic disease was as rare as was once believed. In one case in which there was a definite aneurysm the Wassermann was positive. Dr. Rosenson asked if there were any direful effects from the strain of the tests. He had seen two cases of mitral stenosis without attacks of decompensation, both of which developed definite auricular fibrillation, and went down hill rapidly. These came on after moderately severe exertion.

Dr. BARRINGER said he was interested in the question Dr. Rosenson had brought up in reference to the result of physical over-exertion in cardiac cases. His experience had been quite negative in this respect. Some years ago he had had three cases that showed decompensation after exertion, which required two or three days in bed with the administration of digitalis. Since then he had seen no such case of decompensation due to over-exertion. It was extremely unusual to have decompensation due to over-exertion. As a rule if the attack did not come on two or three hours after the exertion it was due to reinfection. In angina, however, recurrences were often the result of over-exertion.

Dr. L. E. LAFETRA said that although it was a rare occurrence, sudden excessive physical exertion did produce decompensation, and it was important to bear that fact in mind. These cases reported as being subjected to tests were under the supervision of a physician, and in these circumstances there was no danger. There were, however, children who, if they walked rapidly up two or three flights of stairs, would develop acute dilatation at once from cardiac strain. Dr. LaFetra cited such a case, in which the child ran up two flights of stairs and following the exertion an acute dilatation developed, followed by auricular fibrillation, and later by a recrudescence of the cardiac infection, so severe that she died after about three weeks.

Dr. CHARLES HENDEE SMITH confirmed Dr. LaFetra's experience, citing a somewhat similar case. He said he felt sure Dr. Wilson and Dr. Barringer did not give the exercise tests to hearts really organically affected, and he did not believe any damage could result from the exercises as he had seen them given and tried them himself. There had been some criticism of the cardiac classes. It was said that they were making these cardiac children neurasthenics by putting them in classes by themselves. The organic cardiac case was in a class by himself, and the sooner he learned what he could do and what he could not do the better for him. He could be made perfectly cheerful, but he must learn his lesson, and the sooner he learned it the better his chance for a long life. A cardiac class was no more gloomy than a nutritional or any other class. As to the tonsils, he had seen cases in which the tonsils were removed and within three and a half years there was a regrowth of tonsillar tissue.

Dr. HALSEY, in closing, called attention to one great advantage of physical exercise in cardiac cases, that was the effect it produced on their psychology, making these patients more optimistic. The old mental attitude toward heart disease was still practically the rule, and it was only since exercise had been begun in these cases that the mental attitude toward cardiac cases was changed. He wished the confidence of physicians in physical exercise to become such that they would feel safe in going ahead and prescribing exercise, remembering always that there must be a differentiation between individuals with different conditions of the heart muscle. The danger was that in their enthusiasm over the application of exercise in the treatment of heart disease differentiation would not be made, and they would have patients doing twenty pounds of work when they should be doing only two or three pounds, in which case results such as Dr. LaFetra had just related would ensue. The lesson was to be very careful until the patient learned the capacity of his own heart muscle. Children who had been shut out of games and exercise, and who spent their time in bed, improved rapidly when they found they were no longer shut out from all activity. Exercise improved the psychology as well as the physiology.

Dr. MAY G. WILSON, in closing, said she appreciated the question raised by the gentlemen as to the danger of any harm resulting from the exercise tests. She had felt the same way about a year ago, and for this reason first investigated the reactions of normal children. As Lewis advised, she proceeded slowly with cardiacs, first giving simple tests that were not strenuous, and then gradually working up. She did not wish to give the impression that cardiacs had been given test exercises that produced distress. The initial test exercise was always much below the tolerance of the child, and was gradually increased. Of course, it was understood that one did not need to give an exercise tolerance test to a child with cardiac failure; that child belonged in bed.

Dr. WILLIAM ST. LAWRENCE said he thought Dr. Dennett was right and he wished he had had the courage to take out the tonsils in 100 per cent. of the cardiac cases. With reference to Dr. LaFetra's case of heart failure following over-exertion, Dr. St. Lawrence said he had had 25 cardiac children who had been exercising for three or four years, and he had never seen any ill effects from exercise within reason and with moderation. It would be interesting to know whether in the case Dr. LaFetra cited there was any other infection, and whether the child had a temperature before the exertion. It was their custom to take the temperature before allowing exercise, and if the child showed an elevation of temperature it was excused from exercise.

Dr. LAFETRA replied that the temperature was not taken before the child went up stairs. On the other hand, the child had not been showing any elevation of temperature and was being inspected each day. Emphasis should be placed on the fact that these test exercises were given under the supervision of a physician. The cases of heart failure from over-exertion occurred when the children were not under such supervision. He quite agreed that cases of heart failure from over-exertion were rare in children unless there was infection, but they did happen.

AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

Thirtieth Annual Meeting, Held in Atlantic City, September 14-17, 1920.

THE PRESIDENT, DR. WILLIAM MARTIN OF ATLANTIC CITY, IN THE CHAIR.

(*Concluded from page* 877.)

The Treatment of Hemorrhoids by Electrolysis.—Dr. H. W. SIGMOND of Crawfordville, Ind., read this paper. After discussing the history, varieties and causes of hemorrhoids, he stated that he could remove external hemorrhoids, or those situated below or upon the distal side of the mucocutanous line, surgically under local anesthesia without much difficulty, and quicker than he could by electrolysis. Internal hemorrhoids were located above the mucocutaneous line and in dealing with these their electrical treatment was the treatment of

choice. He had tried several methods of treating hemorrhoids by electricity but preferred the positive pole, using the needle. The cambric needle was specially prepared by insulating it by winding silk thread around it for one-fourth inch from the point. The point of the needle was then stuck into a cork for about an eighth of an inch leaving one-eighth of an inch of the needle above the cork. The needle was then shellacked from the upper end of the thread down to the cork, thus leaving the part above the thread unshellacked and uninsulated to fit into the needle holder. The part in the cork was also uninsulated. After the shellac had dried the needles could be removed from the cork and were ready for use. For local anesthesia he used quinine and urea hydrochloride or novocaine. After injecting the pile and waiting a few minutes for the anesthesia to take effect, the negative pole was attached to a large moist pad and strapped to the abdomen so as to make and keep good contact. The positive pole was attached to the needle which was inserted into the pile, carrying the needle in up to the thread. The idea of the thread was to make a shoulder to prevent the needle penetrating too deeply. The current was thus carried directly into the pile. Ten or fifteen milliamperes were used until the pile became decidedly blanched in appearance. The pile should be punctured as nearly the top as possible. For about two days there would be no change in the patient but on the third day relief would come. Each pile was treated separately, using a new needle, because the positive pole caused the needle to roughen and deteriorate so that it might break off when used a second time. This was not a panacea for all rectal troubles, but for all internal piles that were not of the fibrous variety, one could assure the patient of relief by this method.

Report on Phototherapy.—Dr. T. HOWARD PLANK of Chicago presented this report, which was read by Captain Sampson. The writer stated that during the last year much progress had been made in acquainting the profession at large with the benefits to be derived from the use of phototherapy in maintaining and regaining health. They had learned that Rollier's treatment was being used, and apparently with success, at the Adam Memorial Hospital at Prysburg, N. Y. Though Rollier spoke of an analgesic, a bactericidal and sclerogenic action of the solar rays, a clear understanding of the theoretic side concerning the influence of the sun's rays upon the human body had not yet been reached. The sun's rays were divided into two classes, long-waved and short-waved ones. To the latter group belonged the ultra-violet rays. This portion of the spectrum of the sunlight was the therapeutic active one. No doubt it would be taking another great step ahead in the treatment of surgical tuberculosis to establish numerous institutions in our country where Rollier's sun treatment could be used intelligently. But, granted we had the advantages of such institutions there would always be patients who could not spend a year and a half to three years in such institutions waiting for definite cure. All the good results of heliotherapy could be duplicated by the use of phototherapy, actinotherapy being the active portion of the spectrum needed to be used with some caution and should always be preceded by a radiant light treatment for the purpose of increasing the circulation and bringing the blood to the surface. This report reviewed the literature of the past year on the subject of phototherapy and discussed the advantages and disadvantages of the new phototherapeutic apparatus recently placed on the market.

Actinic Rays.—Dr. T. HOWARD PLANK of Chicago presented this paper which was read by Captain Sampson. The writer stated that concentrated actinic rays were little known a decade ago and most of the medical profession did not know of them to-day notwithstanding that they had a definite fixed value in the treatment of many diseases, both local and constitutional. Actinic rays were incapable of inflicting permanent danger even if ever so improperly used, and even the beginner could obtain decided benefit with them, while one who understood the proper technique could get some really marvelous results, and this with a minimum of expense and energy. To the dermatologist they were invaluable; to the internist they meant a decided increase in his success; to the tuberculosis expert they were a great ally, while the genitourinary specialist and the surgeon should not be without them. Actinic rays should not be used alone in most cases but as an adjuvant treatment. The bacteriologists told us that disease germs could not live in these rays, therefore we should use them to help fight germs and win the struggle for existence by the simplest possible natural means. Experiments showed that the rays of the quartz mercury vapor lamp had a greater bacterial effect upon the cocci than upon the bacilli. It was positively known that the rays would destroy streptococci and staphylococci, and they knew from actual use that they would destroy diphtheria bacilli as well as less virulent types of bacteria. All treatments with actinic rays were limited to minutes; many required but one to five minutes and some only one-quarter to one-half a minute to be followed by a definite beneficial result. On the other hand these results were very much more permanent than the length of time of the application would indicate. This measure would remove a port-wine birthmark in a half dozen treatments and remove it never to return. It would stop the itching of eczema in a few minutes. Many cases of tuberculosis began to improve after five to ten treatments, while the pain of an active osteomyelitis was often relieved by a single treatment of ten minutes' duration. Simple prostatitis was likewise frequently relieved by a single treatment of ten minutes' duration. These treatments should be given three times a week. These rays were the best single remedy that the dermatologist possessed for the treatment of psoriasis. Post-influential conditions could be remedied more quickly by the aid of actinic rays than with any other single measure. All these treatments should be preceded by at least a ten minute application of radiant light, given for the purpose of dilating the surface capillaries in order to furnish a greater volume of blood for the absorption of these rays.

Ultra Violet Light as a Medical Adjuvant.—Dr. DONALD MCCASKEY of New York presented this paper, which was read by Captain Sampson. He stated that some very remarkable surgical results had been obtained by the use of ultra violet light, particularly in local infections such as boils, carbuncles, and bacterial ulcerations. Recently it had been shown by the work of Captain Sampson and Captain Hirsh at the Fox Hills Military Base Hospital that the influence of ultra violet light on abnormal prostatic cases was very beneficial. Underlying the question of ultra violet light, however, it was necessary to take a broader view of the medical problems as they presented themselves before us. First and foremost in the analysis of a patient's problem was the blood chemical data, including the blood plasma and carbon dioxide percentage. In the chemistry of the urine was the ratio of the total nitrogen to urea nitrogen and the percentage of ammonia nitrogen which revealed the oxidation index of the patient's motor. Armed with these vital facts, we could then regulate the food intake to act as a medicine, and with the ultra violet light as an adjuvant we could stimulate the anabolic and katabolic cycles of the tissue cells, thus raising the standard of protoplasm resistance and efficiency.

The Continuous Current in Inflammatory Conditions.—Dr. CORA SMITH KING made this presentation in which she spoke more particularly of inflammatory conditions of the sigmoid, bladder, uterine endometrium, and the cervical and vaginal membranes. The sinusoidal current was used with one pad under the sacrum and the other over the abdomen as strong as the patient could comfortably bear it. When the muscles were well synchronized, with the bulb in the rectum but without a rectal tube, a bland soapsuds enema was given. With the proper posture gravity would carry the fluid to the transverse colon. After the patient had evacuated the enema, she was placed in the knee-chest position and two drams of argyrol, 25 per cent., were introduced into the rectum. If there was trouble in the colon, there was usually trouble with the endometrium and cervix. When there was trouble with the uterus, the cases when not of Neisserian origin were mostly due to extensions of colon trouble. The uterus was then tamponed with 25 per cent argyrol and if there was bladder trouble argyrol was introduced into the bladder. The patient was then placed in the dorsal decubitus and large pads were placed across the pelvis, low down over

the pubic bone. The galvanic current was then passed to easy tolerance, three to five milliamperes, gradually raised to ten milliamperes, in the course of 18 to 20 minutes. Under this treatment the patients made remarkable improvement. Dr. King said she had used argyrol alone and the galvanic current alone, but neither alone gave the results that were obtained by this combination. She asked whether these results were, in the opinion of the members, due to ionization.

Dr. FRED H. MORSE of Boston explained why he believed the good results of this treatment were due to ionization. Argyrol in itself was beneficial and the current aided its diffusion through the tissues by ionization. In addition to this there were the other beneficial effects of electrical treatment.

The Adams-Stokes Syndrome.—Dr. J. E. TALLEY of Philadelphia read this paper, in which he said that the prominent symptoms known as the Adams-Stokes syndrome were a sudden marked slowing of the usual pulse rate of the individual, accompanied by attacks of unconsciousness with or without convulsions. Heart block and Adams-Stokes syndrome were not synonymous, for any grade of heart block might persist throughout the patient's life without developing the syndrome. The cause of the seizures, whether they be confined to unconsciousness or also accompanied by fits, was sudden cerebral anemia, due to the abrupt slowing of the ventricular rate. These attacks might be mild or severe. Mild attacks were marked by vertigo, faintness, pallor, loss of consciousness and absence of ventricular beat. Severe seizures arose where the ventricular standstill lasted fifteen minutes or more. Here venous engorgement caused pallor to give away to cyanosis; to unconsciousness was added twitching of the face, or an arm, and occasionally the fits might become generalized. In these attacks the patients did not pass urine or bite the tongue. In the mild cases breathing might be normal; in the severe attacks stertorous and apneic. The only suggestion of an aura was that at times the patient was aware of the slowing of the ventricular rate, with varying pauses between beats, from a normal rate to one of 30 per minute. A single period of ventricular standstill of from three to seven seconds would usually cause unconsciousness, fifteen seconds or more caused convulsions in addition. The seizures occurred most frequently in subjects suffering from permanent progressive complete heart block. They also occurred in incomplete dissociation with a permanent ideo-ventricular rhythm well established. The immediate cause of the seizures might usually be traced to some unusual physical activity. The outlook depended upon the extent of the myocardial degeneration and the frequency and severity of the fits. Sudden death in a first attack was rare. The majority of these patients died of progressive heart failure finally without cerebral symptoms. This fact should not make one underestimate the gravity of these seizures. Even a mild attack of unconsciousness called for a period of absolute rest in bed. A single injection of atropine sulphate, 1/50 of a grain, might be tried. To prolong the effect 1/100 of a grain of atropine sulphate by mouth to physiological effect was worthy of a trial. Heart stimulants such as digitalis and strophanthin were mostly contraindicated. Electrocardiograms from various cases of heart block illustrated the paper.

Vaccine and Gland Therapy as an Aid in Our Practice During the Past Twenty Months.—Dr. J. W. TORBETT of Marlin, Texas, presented this communication, in which he stated that in a series of 4686 mostly chronic cases of all kinds treated in their institution during the past twenty months 27.7 per cent. gave a history of having had influenza as one possible cause of their trouble. Many still had a leucocyte count of less than 5000—often as low as 3500. Such a count was seen in both influenzal and malarial cases. Many more, with them 23 per cent. last year and 27 per cent. this year at the Battle Creek Sanitarium, had the polymorphonuclears less than 60 per cent.; at times as low as 31 to 45 per cent. Of all their post-influenzal cases, 25 per cent. showed a peculiar lung haziness by the fluoroscope which was confirmed by the *x*-ray. Many more infected tonsils and sinuses were found than in previous years. The mixed influenza and pneumococci vaccine (Rosenow's) greatly aided other means in restoring health in all cases with leucopenia or polymorphopenia, when a reaction was secured. If no reaction was secured phylacogens were given carefully in the veins, with three-grain doses of sodium cacodylate in the chronic anemic cases. One or more of the seven types of rational therapy were always used: (1) If possible, all foci of infection were found and removed. (2) Elimination should be promoted through the lungs, skin, bowels, and kidneys by physiotherapy and other means. (3) Nutrition should be cared for by balanced ration with a slight excess of alkaline bases. (4) Immunity should be conferred by vaccines, if possible (5) Specific chemotherapy should be employed in cases of lues, malaria, diphtheria, and deficient gland action. (6) There should be alternate exercise, rest, and sleep. (7) Psychotherapy should be employed in any form to arouse hope and optimism. Thyroid extract greatly helped those with dry skins, dry, falling hair, slow speech, lowered tolerance for cold and meats. Mammary gland was indicated for menorrhagic girls with poorly developed breasts and for menorrhagic women at the menopause, with pituitrin added if constipation was present, or if the muscles were flabby or beginning fibroid was suspected. Ovarion substance was indicated for amenorrhea and cystic ovaries, tincture of iodine being painted over the ovaries twice daily.

Treatment of Fractured Patella; Diathermy.—Dr. DOUGLAS A. CATER of New Jersey read this paper, in which he related the case of a young man, about 35 years of age, who stepped off his back stoop in the dark and fell, striking his knee on the flagstone and fracturing his patella. An *x*-ray of the knee showed the patella broken into four distinct pieces. After reducing the swelling by firm strapping and employing daily massage by an experienced masseuse, it was found that the fragments could be coapted by suitable splints and adhesive plaster. After eight weeks in bed with the leg raised on an inclined plane, all apparatus was removed and good union was found to have taken place. There was considerable atrophy of the thigh and to a less extent of the calf This atrophy he had tried to forestall by having the splints removed every day for two weeks for massage, but stopped the massage for fear of disturbing the approximation of the fragments. The knee was also very stiff, there being a range of motion of only about 10 degrees. Treatment by diathermy was instituted, lasting at first twenty minutes and then thirty and forty minutes. This was followed by the statis wave with glass vacuum electrode to the thigh and leg muscles for five minutes. The diathermy technique was substantially that used by Captain Sampson at the Government Hospital at Fox Hills, and consisted of two block tin electrodes, moistened with soapy water, about two inches wide, one encircling the thigh above the knee and a similar one below the knee. These were held in place by elastic mesh bandages to allow for swelling of the limb. The current strength was up to 1,500 milliamperes. This was supplemented by daily active and passive motion. Improvement began at once and at the end of a week flexion had increased to above 20 degrees. After three treatments a week for six weeks 35 degrees flexion was obtained. After consultation with Dr. Price the treatments were given every day for a time. Improvement was steady until the patient could flex his knee at right angles. Eleven months after the accident both extension and flexion were normal. This case was of interest in showing that good bony union could sometimes be obtained in fracture of the patella without operation and because it showed what diathermy would do in breaking up stiff adhesions and doing it painlessly.

The following papers were read by title: "Results of Physical Modalities in the Treatment of Pulmonary Tuberculosis," by Dr. J. D. Gibson of Denver, Col.; "Exophthalmic Goiter Successfully Treated by Physical Measures," by Dr. A. Brustad of San Antonio, Tex.; "Treatment of Some Chronic Diseases by the Elicitation of the Spinal Reflexes with the Sinusoidal Current," by Dr. L. C. Sammons, Shelbyville, Ind.; "The X-Ray in Uterine Hemorrhage and Allied Conditions," by Dr. George I. Forbes of Burlington, Vt.; "X-Rays and Radium in Gynecology," by Dr. Foveau deCourmelles, Paris, France; "The Technique and Interpretations of Radiographs of the Nasal Accessory Sinuses," by Dr. W. H. Mick of Omaha, Neb.; "Experiences in

Treating Hay Fever with High Frequency Current," by Dr. William T. Lewi of Albany, N. Y.; "Information Our Patients Should Have, with Special Reference to Radiodiagnosis," by Dr. Sinclair Tousey of New York; "Cooperation Between Surgeons and Physiotherapists," by Dr. G. E. Deering of Worcester, Mass.; "Summary of Reasons for the Need of Securing Structural Poise—Equilibration—Stabilization," by Dr. J. Madison Taylor of Philadelphia; "Peripheral Facial Paralysis—Bell's Palsy; Its Treatment by Electrotherapeutic Measures," by Dr. J. Irwin Swain of Erie, Pa.

Miscellany.

The "Sign of the Tongue" in Verminosis.—Couillaud has described a phenomenon said to occur in ascarides and oxyuris diseases. The fungiform papillæ in the hosts to these worms are hypertrophic and if one examine the base of the tongue he will behold the scattered red points which are also diffused along the sides and at the tip. The rationale of the phenomenon is obscure, but the author insists that it is to be seen only in certain halminthiases.—*La Presse Médicale.*

Seaplane Ambulance.—The following incident illustrating the efficient service of the Navy Medical Corps and of the Naval Air Service received editorial comment in the Pittsburgh *Chronicle-Telegraph* of August 2. A pharmacist's mate, the only man among the eighteen sailors stationed there having any medical knowledge, was stricken with appendicitis. The station is some 200 miles from the naval base at Hampton Roads, is utterly isolated, distant from routes of travel by rail or water, and quite out of reach of ordinary medical aid. To send a motor boat or other water conveyance for a doctor would mean a long journey and much delay. A radio message was therefore sent to the commanding officer at Hampton Roads, reporting the situation. Capt. James C. Pryor, U. S. N., commanding the naval hospital there, explained the case to Rear Admiral A. F. Fechteler, U. S. N., and Lieut. (T) William Moore, Medical Corps, U. S. N. R. F., was ordered to Cape Hatteras in a seaplane. The machine arrived there at 1.15 o'clock in the afternoon, Lieutenant Moore diagnosed the case as one of acute appendicitis. The patient was placed in the seaplane, which arrived at Hampton Roads at 6.45 o'clock, the voyage of 400 miles having been made in five and one-half hours. The patient was at once taken to the hospital and at last accounts was recovering from the operation.—*Army and Navy Journal.*

Work of the Institute of Radiology at Monte-Video.—The official report of this institution for the year 1919 shows to what extent these methods of diagnosis and therapeutics are extending over the habitable globe. The institute began its activities in 1914 and in the six years following the total number of patients was over 20,000, the number increasing from 1,493 in 1914 to 5,232 in 1919. The special service was as follows for the expired year: Radioscopies, 3,233; radiographies, 2,307; applications of *x*-rays, 2,965; applications of radium, 5,090, and applications of phototherapy, 699. The money disbursed for the six years for installation and operating expenses is nearly $65,000; and presumably because the installation is now fairly complete the expenses for 1919 were about $7,500 only. During 1919 the following subjects were given special attention: radiodiagnosis of the spondyloses; radiodiagnosis of rheumatic gout; radium therapy of exophthalmic goiter; radium therapy of certain affections of the eye, nose, etc.; phototherapy of leucoplakia vulvæ; investigation of the national minerals for radioactivity. A museum department is well under way. The director of the institute is C. Butler.—*Anales de la Facultad de Medicina de Montevideo.*

Anthrax Mistaken for Erysipelas.—A case of this sort is reported by Bouwmeester in the *Nederlandsch Tijdschrift voor Geneeskunde* for June 26, 1920, lxiv, 1, 26. The patient was 51 years old, who summoned medical aid on March 29. Four days before, the affection began on the right side of the neck. The diagnosis was eryispelas. At the hospital the patient was seen to have a sick look and a temperature of 39° C. He confessed to being an alcoholic. The parts were red and swollen and the continuous area with the neck participated in the process. About midway over the sternomastoid muscle and in the center of the swelling was a special necrotic lesion that suggested the possibility of anthrax. It was noted that the swelling was hard and brawny. Anthrax bacilli were cultivated from the secretion of the sore, a platinum loop having been passed into a slight incision. The patient was at once placed upon anthrax serum and improved slowly, being discharged cured on May 22, after having spent nearly two months in the institution. He had been exposed to several suspicious objects. He had cut his neck while shaving and had used at that time a new shaving brush. This was submitted to an intensive bacteriological analysis, but nothing was found to show that it harbored anthrax germs or spores. The incubation period after inoculation with anthrax germs is never more than three days, so that a history of exposure to sheep and hides at a somewhat remote period was regarded as of no moment and the brush was adjudged guilty despite the negative finds.

"Domestic Measures."—H. O. Gunewardene makes a plea for compulsory restraint on the use of "domestic measures" in the administration of medicine. He made observations on spoons supplied to him by different people and his findings were that spoons fall mainly into three different groups: (*a*) Size A, half a drachm to one drachm when just full; 2. Size B, one drachm when just full; 3. Size C, equivalent to twice size B, or equal to two drachms, when just full; with some occasionally varying in size and capacity between A, B and C. (*b*) Tablespoons. 1. Size A1 just full, equivalent to half an ounce; 2. Size B1, equivalent to twice A1 just full, equivalent to one ounce. (*c*) Dessertspoons. 1. Size A2 just full, equivalent to two drachms; 2. Size B2, equivalent to twice A2 just full, equivalent to half an ounce. By just full, is meant only so full that the spoon can be held by an average person without any overflowing. The use of spoons of capacity equivalent to the dose prescribed, of marked bottles, and the tolerance to bigger doses than are prescribed, as well as the taking of smaller quantities than are advised, have prevented more noticeable ill-effects; but ill-effects do occur, which are not only very unpleasant but sometimes even dangerous or disastrous.—*The Practitioner.*

THE ANXIETY NEUROSIS.

BY H. LAVESON, M.D.,

NEW YORK.

ESPECIALLY valuable for medicine has been Freud's sharp differentiation of the symptom complex of the anxiety neurosis from the clinical picture of neurasthenia. The name anxiety neurosis arises from the fact that the various components of this symptom complex are grouped around the cardinal symptom of anxiety to which each individual symptom shows a definite relationship.

Clinical Symptomatology.—The clinical picture of the anxiety neurosis comprises the following symptoms:

1. General irritability and irritation: A special point of value is the expression of this heightened irritability through a hyperesthesia for visual impressions, but especially through a hyperesthesia for sounds, hypersensitiveness to noises. This is also frequently the cause of sleeplessness of which more than one form belongs to the anxiety neurosis.

2. Anxious expectation: This condition can be best illustrated by example. A lady, for example, who is suffering from anxious expectation, thinks of pneumonia every time her husband, who has catarrh, has an attack of coughing and sees in her mind his funeral passing by. If on her way home, she sees two persons standing together in front of the door, she cannot help thinking that one of her children may have fallen out of the window; when she hears the bell ring, some one is bringing bad news, etc., while in all these cases there is no especial occasion to strengthen such a mere possibility. For one form of anxious expectation, that in respect to the person's own health, one cannot avoid the old name, hypochondria.

A further expression of anxious expectation is the frequent tendency to anxiety for certainty found in persons of great moral scrupulousness, which likewise varies from the normal up to scepticism.

The anxious expectation is the nuclear symptom of the neurosis; in it may plainly be seen a part of the theory of the same. It can be said that there is here a quantity of free-floating fear (angst) at hand which in the expectation rules the choice of ideas and is always ready to attach itself to any passing idea.

3. The anxiousness which is constantly present can, however, also break through into consciousness suddenly, without being awakened by the course of ideas thus causing an attack of anxiety. Such an anxiety attack may consist either of an anxious feeling without any associated idea or of the idea of impending death or of a stroke or some paresthesia may be mixed with the anxious feeling, or finally, with the feeling of anxiety may come a disturbance of one or more of the bodily functions, the respiration, circulation, vasomotor innervation, glandular functions, etc. Out of this combination, the patient emphasizes now one, now another factor; he complains of heart cramp, dyspnea, sweating, ravenous appetite, etc., and in his representation the anxious feeling frequently becomes obscured or becomes really unrecognizable and described as a "bad feeling" of indefinite discomfort.

4. There are therefore rudimentary attacks of anxiety and equivalents of the anxiety attack of which Freud has prepared the following list:

(*a*) Disturbances of the heart's action, palpitation with brief arrhythmia, with longer attacks of tachycardia up to severe conditions of cardiac weakness, the differentiation of which from organic affections of the heart is not always easy—pseudo-angina pectoris, a delicate diagnostic field.

(*b*) Disturbances of respiration: many forms of nervous dyspnea, asthmatic attacks, etc. These attacks, however, are not always accompanied by recognizable anxiety.

(*c*) Attacks of sweating, often nocturnal.

(*d*) Attacks of shaking and trembling, which may only too easily be taken for hysteria.

(*e*) Attacks of ravenous appetite often accompanied by vertigo.

(*f*) Diarrhea in the form of attacks.

(*g*) Attacks of locomotor vertigo.

(*h*) Attacks of so-called congestions about everything which has been called vasomotor neurasthenia. Here may be mentioned the vasomotor edemas, the sudden dying of a finger, an arm, or a foot (angina pectoris vasomotoria).

(*i*) Attacks of paresthesias (these, however, seldom without anxiety or a similar feeling of discomfort).

5. Nothing but a variety of anxiety attack are the frequent night terrors (favor nocturnus of adults) commonly accompanied by anxiety, dyspnea, sweating, etc. This disturbance occasions a second form of sleeplessness in the framework of the anxiety neurosis. In addition, the pavor nocturnus of children shows a form which undoubtedly belongs to anxiety neurosis. It frequently has an hysterical touch which makes it appear as something special and brings it into closer connection with the anxiety hysteria which will be discussed later.

6. A prominent place in the symptomatology of the anxiety neurosis is occupied by vertigo which, in its lightest forms, is better designated as giddiness, in its severer types as "attacks of vertigo" with or without anxiety, which belongs to the se-

verest symptoms of the neurosis. This vertigo never leads to complete loss of equilibrium. On the other hand, it seems possible for such an attack of vertigo to be replaced by an attack of profound weakness. Other fatigue conditions of the anxiety neurosis appear to depend on a heart collapse. Dizziness at high altitudes, on mountains and precipices, likewise frequently accompanies anxiety neurosis.

7. On a basis of a chronic anxiousness (anxious expectation) on the one hand, and a tendency to attacks of vertigo on the other, two groups of typical phobias develop, the first in regard to general physiological menaces, the other in regard to locomotion. To the first group belong the anxiety over snakes, thunder, darkness, vermin, and the like, as well as the typical moral overscrupulousness.

Forms of scepticism; here the unattacked anxiety is plainly applied to the strengthening of doubts which are instinctively implanted in every person.

The other group embraces agoraphobia with all its varieties collectviely characterized by its relation to locomotion. A preceding attack of anxiety is here frequently the foundation of the phobia.

8. The digestion in anxiety neurosis undergoes only a few, but characteristic, disturbances. Sensations like a tendency to nausea and vomiting are not rare and the symptom of ravenous appetite, either alone or with other congestions, can give something of a rudimentary attack of anxiety. A chronic change, analogous to the anxious expectation, is found a tendency to diarrhea which has given occasion for the strangest diagnostic errors. The diarrhea is the analogue of the frequent micturition of the anxiety neurosis.

9. The paresthesias which may accompany the vertigo or attack of anxiety are of interest because of the fact that they are associated in a regular sequence like the sensations of the hysterical aura. Nevertheless, these associated feelings, in contrast to the hysterical are atypical and changeable. A large number of so-called rheumatic patients really suffer from anxiety neurosis. In addition, many cases of anxiety neurosis show a tendency to hallucinations; these cannot be considered hysterical.

10. Many of the so-called symptoms which accompany or replace the anxiety neurosis appear in chronic form. This applies especially to the diarrhea vertigo and the paresthesias.

Occurrence and Etiology. — These symptoms which Freud describes indicate very clearly the presence of the endocrine factors and correlated disturbances of the sympathetic nervous system. The condition of general irritability is what we expect from an abnormal amount of thyroid secretion in the blood. It is altogether like that which occurs with Graves' disease, or can be produced by the administration of thyroid. The palpitation, diarrheal attacks, and other symptoms are apparently the same as those occurring with hyperthyroidism of other origin. The vasomotor symptoms and others referable to the sympathetic nervous system might indicate the presence of an excessive secretion of adrenalin or might be the effect of thyroid bodies themselves.

As already explained, the morphology of this malady is the corrollary of a typical etiology which makes it preferable to consider men and women separately. Anxiety neurosis occurs in females classified according to their age and positions in life in the following cases:

(*a*) Anxiety of virgins or adolescences. A number of indisputable observations have shown that a first experience with the sexual problem, a rather sudden revelation of what up to that time had been veiled, for example by the sight of the sexual act or by the male genitals, by a lecture, printed or pictorial representation, can cause an anxiety neurosis in a maturing girl which is combined with hysteria in an almost typical manner.

(*b*) Anxiety of the newly married, young women who have remained anesthetic during the first cohabitations often develop an anxiety neurosis which disappears again after the anesthesia has given way to a normal feeling. Total anesthesia is not meant here, but that of those women who are excitable up to a certain degree but are incompletely gratified.

(*c*) As anxiety of women whose husbands exhibit ejaculatio præcox or a very diminished potency.

(*d*) Anxiety of women whose husbands practise coitus interruptus or reservatus. These last two cases belong together, for it is easily proven from the analysis of a great number of cases that the occurrence depends on whether or not the woman is gratified during coitus. In the latter case the ground is prepared for the outbreak of an anxiety neurosis. On the other hand, if the husband can gratify the woman either through a better performance of the act or by preventing ejaculation at the beginning of the act, she remains free from anxiety neurosis. The congressus reservatus by means of a condom exposes the woman to no injury if she is very easily excited or the man very potent; in other cases this kind of conception-preventing intercourse is not less injurious than the other forms.

(*e*) As anxiety of widows and intentional abstainers, often in typical combination with obsessions.

(f) As anxiety in the climacteric, during the last great climax of the sexual appetite.

Classes *c*, *d*, and *e* embrace the conditions under which the anxiety neurosis begins most frequently in the female sex and earliest, independent of hereditary disposition.

For the conditions of the anxiety neurosis in men, Freud has formulated the following groups analogous to those found in women:

(*a*) Anxiety of intentional abstainers, frequently combined with symptoms of defense (obsessions, hysteria).

(*b*) Anxiety of men as a result of unsatisfied excitement (during the engagement period), further, of persons who through fear of the results of sexual intercourse content themselves with fondling and looking at the woman. This group of conditions (which is also transferable unchanged to the other sex), engagement, relations with sexual forbearance, afford the purest cases of the neurosis.

(*c*) Anxiety of men who practise coitus interruptus, therewith delaying the ejaculation until the woman is gratified. This form of anxiety neurosis in men is usually mixed with neurasthenia.

(*d*) Anxiety of men in the senium. There are men who have a climacteric like that of women.

and at the time of their diminishing potency and increasing libido, develop anxiety neurosis.

For both sexes, the two following classes apply:

(*e*) Neurasthenics as a result of masturbation fall into anxiety neurosis as soon as they forego their method of sexual gratification. These persons have rendered themselves especially unable to stand abstinence.

It is here important for the understanding of the anxiety neurosis to notice that a very serious case of this condition occurs only in men who remain potent and in women not entirely anesthetic.

(*f*) Anxiety neurosis arises in both sexes occasionally from overwork, exhausting exertion, for example, night watching, nursing the sick, and after a severe illness.

In addition to the results of his observations, Freud has sought to give a theoretical interpretation of the pathogenesis of anxiety neurosis in which he takes into account the observation that many cases of anxiety neurosis accompany an appreciable lessening of the libido or psychic pleasure.

In the points adduced thus far concerning the anxiety neurosis there are sufficient stopping points from which to gain a view of the mechanism of this neurosis. One gains the impression that it has to do with an accumulation of excitement; that the anxiety which corresponds to this accumulated excitement, as psychic anxiety which finds no outlet, is of somatic origin; and further that the accumulated excitement is of a sexual nature. These hints favor the expectation that the mechanism of the anxiety neurosis is to be sought in the diversion of the somatic sexual excitement from the psychic and in the abnormal application of this diverted excitement caused thereby. This idea of the mechanism of the anxiety neurosis can be made clearer by a consideration of the normal sexual process, at first only as it occurs in men. The normal sexual act may be sketched as follows: First there is an accumulation of somatic excitation; this increases to a point where it occasions a psychic irritation, creating the libido; finally this is discharged by a complicated spinal reflex act which must also carry off the psychic excitement simultaneously. Such a psychic discharge is only possible by the way which Freud has called adequate or specific action. The etiology of true neurasthenia and anxiety neurosis finds its place in the outline of this representation of the sexual process, which in essentials is also applicable to the woman. Neurasthenia ensues every time the adequate discharge is replaced by an inadequate one as when normal coitus under favorable conditions is replaced by masturbation or spontaneous pollution; all agencies, however, which hinder the psychic utilization of the somatic excitement conduce to anxiety neurosis.

The previously described etiological conditions of anxiety neurosis disclose the common characteristic of accumulation of excitement. Intentional abstinence constitutes the first etiological factor for the man in that it prevents the specific action which should follow the libido. The somatic excitement is thus accumulated and is discharged in other ways. In this way, abstinence leads to anxiety neurosis. Abstinence is also the real factor in the second etiological group, that of frustrated excitement. The third class, that of coitus with precautions (reservatus) acts injuriously by disturbing the psychic preparation for the sexual discharge since it interposes another diverting psychic task before allowing the completion of the sexual act. Anxiety in the senium (climacteric of men) demands another explanation. There is here, as in the climacteric of women, such an increase in the production of somatic excitement that the mind proves relatively inefficient to care for the same.

The etiological conditions in the woman may without difficulty be viewed from the same standpoints. In addition, the disagreement, between the somatic and the psychic in the course of the sexual excitement can occur earlier in the woman and is more difficult to remove than in the man.

Thus, the Freudian view considers the symptoms of the anxiety neurosis as substitutes in a way for the omitted specific action which should follow the sexual excitement.

As a further corroboration of this view, it should be remembered that also in normal coitus the excitement is accompanied by acceleration of the respiration, palpitation, sweating, congestion, etc. In the corresponding attack of anxiety of our neurosis, there are the ryspnea, palpitation, etc., of coitus isolated and exaggerated.

In those exceptional cases which do not arise from specific causes but from other banal injuries, such as nursing the sick, overwork, etc., the sexual etiology is indeed absent, but the illness is established on the foundation of a sexual mechanism, since general exhaustion renders the mind unable to care for the somatic excitement which continually makes demands on it.

This reference to the exceptional causes of the anxiety neurosis is always overlooked by the critics who, in opposition to Freud, think they have found anxiety neurosis without sexual injury. This explanation of a sexual mechanism replacing a sexual etiology is, however, a very important one, and it is easy to make the same one for those very similar cases of neurasthenia not of sexual etiology, for example, those occurring with arteriosclerosis. In these conditions the disease may also arise from indirect disturbances of the elaboration of sexual products, like the primary disturbances of other organic processes. By the substitution of a sexual mechanism for the sexual accidents, there may result a progress in the comprehension of the true neurosis similar to that which the theory of the psychoneuroses experienced when the importance of the sexual traumas was replaced by infantilism of sexuality.

Refutation of the objections brought against the sexual etiology of anxiety neuroses.—As already mentioned, the formerly much greater field of the neuroses has been lessened by the diseases of the blood-forming glands. Neurasthenia and anxiety neurosis constitute the transition from the sexual neuroses to such exquisite toxic diseases of the nervous system. They are caused by disturbances of sexual processes in the organism which we must call chemical. Further, they actually show a great similarity to the phenomena of intoxication and abstinence; the similarity to Basdow's and Addison's diseases is obvious.

Freud in his assertions regarding the etiology of the true neuroses knew that in bringing forward

the sexual etiology he adduced nothing completely new, for the undercurrents in medical literature which took this fact into account have never disappeared. Indeed, in many of these undercurrents, the cure of "sexual difficulties" and "nervous weakness" has been united in a common promise. Further, the official medicine of the schools has really noticed these relations, although it has acted as if it knew nothing of them. It may easily be perceived that a dim perception of the predominating importance of sexual agencies in the production of nervousness, such as Freud has recently sought to establish scientifically, has never been absent from the consciousness of the laity, as many of the native but fundamentally correct expressions of patients concerning the cause of their troubles indicate.

The chief objection to Freud's assertion of a sexual etiology of the anxiety neurosis concerns the fact that abnormal relations of the sexual life are so exceedingly frequent that they must always be at hand whenever sought. Thus, the existence of these in cases of anxiety neurosis cited does not prove that the etiology of the neurosis lies therein. Further, the number who practise coitus interruptus and the like must be incomparably greater than the number afflicted with anxiety neurosis. In reply to this, it may be asserted that in the recognized tremenddous frequency of the neuroses and of anxiety neurosis in particular, one ought not to expect to find a rare etiological agent; further, that a postulate of pathology is actually fulfilled in this case, namely, that in the investigation of etiology, the etiological agent must be proved more frequent than its result, since for the latter other conditions (as disposition, total of specific etiologies, other banal injuries) may be required; finally, that the detailed analysis of suitable cases of anxiety neurosis proves the significance of the sexual agency beyond dispute.

Perhaps many a one who is entirely ready to take into account the sexual etiology of the nervous malady will still repudiate it as one-sided because he is not requested to direct his attention also to the other agencies commonly mentioned by the authors. It is far from Freud's intention to substitute the sexual etiology of the neuroses for every other, hence he would explain that the efficiency of these remains. Freud means rather that in addition to all the known and probably rightly recognized etiological agencies of the authorities are added the sexual which have not been sufficiently appreciated. It should not be forgotten that the etiological problem of the neuroses is at least as complicated as that of other diseases. A single pathogenic influence is almost never sufficient; for most, a combination of etiological agencies is necessary, which aid one another and which cannot be brought into opposition to one another. The sexual agencies in the etiology of the neuroses deserve, however, according to Freud's estimate, to be assigned a prominent place in the etiological series. For only these will be found missing in no case, these alone are able to produce the neurosis without other assistance, so that the other agencies seem reduced to the role of predisposing or supplementary causes; these alone enable the physician to recognize certain relations between the variety and multitude of clinical pictures. Heredity, which is so strongly emphasized by most authors, is undoubtedly an important factor where it is found; it permits a severe case of illness to result where otherwise only a very mild one would have ensued. Heredity alone is inaccessible to the physician's efforts, while the sexual causes are just those which offer him a good opportunity for his therapeutic activity. The agency of overwork which physicians so gladly tell their patients is the cause of their neurosis, is subjected to excessive abuse. The physicians will have to accustom themselves to explaining to the official who has "overtaxed" himself in his office or the housewife whose household duties have been "too hard," that they are not sick because they have sought to perform duties really easy for a civilized brain, but because they have in the meantime grossly neglected and stifled their sexual life. Whoever approaches the cases from this side will find the proof of how valuable for the anamnesis are these points of view. Naturally, he who would convince himself from his patients whether or not their neuroses are really connected with their sexual life cannot avoid making express inquiries regarding their sexual life and giving a truthful explanation of the same without being diverted from this medical duty by ethically colored arguments. It would facilitate his task if the patients might know with what certainty the trained physician can now detect the meaning of their neurotic difficulties and the inference from these to the real sexual etiology. The semblance of negative cases without sexual etiology, which might be given by a negative result of the examination, is explained by the fact that behind such cases is an anxiety hysteria or obsessional neurosis which the actual neurosis merely imitates. Such hysterias in the form of neurasthenia are not at all rare; a more pentrating investigation by means of psychoanalysis invariably unmasks them. For the very frequent mixed forms of true and psychoneuroses, it is recommended in many cases to overlook at first the psychoneurotic component in the clinical picture and to combat therapeutically the true neurosis; in this way one can sometimes succeed in becoming master also of the separated psychoneurosis.

The anxiety neurosis is such a widespread malady that it is daily encountered in practice. Its prevention would be a weighty social task; still, the elimination of certain injuries is dependent on so many material and social factors that an ideal accomplishment of the task under present civilized conditions is not to be thought of. This much can be said, that only an individual who has no great sexual appetite can endure abstinence and that the entire abstinence before marriage is not to be generally recommended, let alone demanded, since it can lead in many cases to deficient capacity for work and indeed directly to a neurosis. Still, complete abstinence is repeatedly harmless just as frustrated excitement, or methods of imperfect gratification are. Finally, if its necessary for a married couple to go without children, harmless measures for the prevention of conception must be employed which are suited to the tolerance of the individuals participating. Thus, here again, just as in the prophylaxis of neurasthenia, it is shown that these neuroses are rooted in a true sense in our whole present-day sexual morality and that only a thorough change

of our entire social and economic organization can bring humanity the solution of the old inherited evil of nervousness.

511 East Eleventh Street.

A SURVEY OF GASTROINTESTINAL METHODS.*

By JOHN L. KANTOR, M.D.,

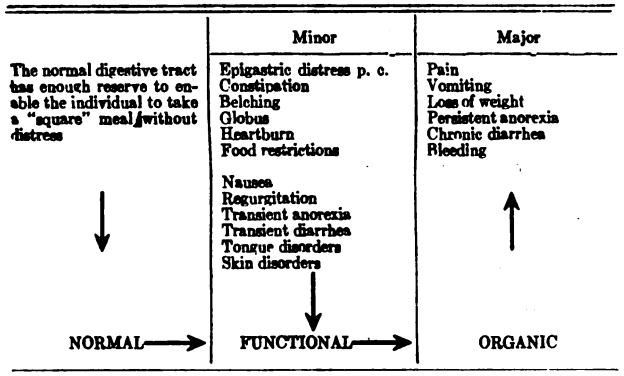
NEW YORK.

CHIEF IN GASTROINTESTINAL DISEASES, VANDERBILT CLINIC, COLUMBIA UNIVERSITY.

It is the object of this paper to present in a simple way a brief but reasonably comprehensive plan of examining the digestive tract, based on methods which have been shown to give the greatest return, for the time and effort expended, in useful, practical information.

Before taking up in detail some of the basic methods employed in the diagnosis of digestive diseases, let us consider two important characteristics of the gastrointestinal tract. In the first place, we know that it is a matter of some thirty feet from mouth to anus, and that it takes about thirty hours for a meal to travel that distance. In the second place, we know that the digestive tube is under the control of a special block system regulated by a series of mechanical, chemical and nervous factors so linked together as to make the tract responsive not only to its own intrinsic disorders but to those arising almost anywhere in the body. Hence, we must keep in mind from the start two points of practical importance. First, owing to the length of the tract and the length of the digestive cycle, the complete diagnosis of a given case of dyspepsia is more likely to require a long, rather than a short, study in symptoms; and, secondly, many a so-called dyspeptic may have an underlying phthisis, or nephritis, or hypertension, or some other systemic condition, which might just as well be recognized by the first doctor he sees as by some subsequent consultant.

A SCHEME OF DIGESTIVE SYMPTOMS.



The History.—Coming now more directly to our subject, we face the question: How shall we go about finding the cause of a patient's trouble? Undoubtedly the most obvious method is the anamnesis as elicited from the patient. The more one knows about the natural history of digestive disorders the more quickly can one begin the process of narrowing down the possibilities suggested by the patient's story. It is a good practice to begin a cross-examination by asking for the chief complaints and then to develop the history in strict chronological order from the very beginning of symptoms. Sometimes the patient loses sight of early significant details. In such a case it is particularly useful to keep in mind what might be called the minor symptoms of dyspepsia. These are commonly: epigastric distress after meals, constipation, belching, globus, heartburn, food restrictions. Perhaps less often we have nausea, regurgitation, transient anorexia, transient diarrhea, skin and mucous membrane disorders, including those of the tongue. It is obvious that any or all of these may be purely functional manifestations. (See diagram.)

As the history unfolds, a tentative opinion can be formed as to the organic or neurotic nature of the case in hand, with this practical proviso, that any patient showing one or more of the "major" symptoms of indigestion—pain, vomiting, loss of weight, bleeding, persistent anorexia, chronic diarrhea—should be regarded as suffering from organic disease until proven otherwise.

The Physical Examination.—A preliminary general physical survey should never be omitted because in every careful study of patients presenting gastrointestinal lesions a very considerable number of people are found to be suffering from lesions originating elsewhere than in the digestive tract.

A great deal of help can be obtained from sizing up patients in respect to their body habitus. By classing individuals as sthenic or asthenic, stocky or slim, erythic or ptotic, carnivorous or herbivorous, plethoric or lymphatic, depending on the nomenclature we choose to follow, we do something more than pay our respects to the external appearance of the body. It is in this way that we learn to utilize the important principle that body form determines visceral form, and that visceral form, in turn, determines visceral function. From this point of view, the finding of a low liver in a stocky person would generally speak for enlargement; in a slim person it would mean only ptosis. Similarly, in a stocky person a six hour barium residue in the stomach might mean pyloric obstruction, whereas in a slim person it would mean nothing more than a severe atony associated with the ptosis.

By physical examination we are enabled also to check up in a certain sense the amount of importance to be attached to the subjective complaints of the patient. Often, in palpating an abdomen, we elicit points of tenderness, most commonly in the epigastrium or in the right iliac fossa, quite unassociated with rigidity. Are we pressing near the hypersensitive plexuses of a neurotic, or do we have to deal with a local lesion? We owe to Dr. Libman, of New York City, a very simple test which can be applied to decide such questions. Firm pressure over the styloid process, just behind the angle of the jaw, is painful to most people. With a little experience it is easy to form an impression of the amount of complaint made by a "normal" person when this pressure is applied. If an individual winces inordinately he may safely be put down as hypersensitive; if he remains indifferent he may properly be classified as hypo-

*Read before the Lackawanna County Medical Society, Scranton, Pa., September 28, 1920.

sensitive. The more one uses this procedure, the more confidently will he avail himself of this method as a useful yardstick in differential abdominal diagnosis. In just the same way, the response of the knee-jerks may be utilized as a rough measure of general nervous irritability.

The Glenard belt test should be incorporated as a routine part of the examination. This test is performed by supporting the lower abdomen while the patient is standing and noting whether there is a welcome relief from some of the symptoms, such as a feeling of weight, drag, or dull pain in the abdomen or back. A positive response gives a useful therapeutic indication.

As an integral part of the physical examination the patient's weight should be noted. It is really surprising how often this is neglected and yet a continuous weight record is just as important in a "stomach" case as is a temperature chart in a fever case. The scales are practically indispensable in studying such conditions as pyloric obstruction, suspected malignancy, and chronic diarrhea, for example. Offtimes nothing is so effective in combatting the hypochondriasis of a neurasthenic as the objective demonstration of a half pound gain in weight since the last visit.

After the completion of the physical examination the physician is in a position to decide whether the case is of sufficient gravity to require the use of more special gastrointestinal methods. In addition to those very sick patients in whom complete studies are urgently needed there are two other groups which in practice often require thorough examination. I refer first to recent dyspeptics of cancer age, and secondly, to certain neurotics whose only hope of cure lies in a sympathetic and detailed analysis of their trouble.

Tube Findings.—The chief function of the stomach tube is the recovery of stomach contents. With a good apparatus, such as the Ewald evacuator, this end can be accomplished quickly, completely, and with a minimum of discomfort to the patient. The examination is best begun in the morning, aspiration of the fasting stomach being one of the most useful procedures in gastroenterology. This test alone enables us to diagnose three things: hypersecretion, gross retention, and gastric bleeding (the last is uncommon). After the fasting stomach is evacuated a test meal may be administered. It is important to bear in mind that a test meal is a definite amount of a definite kind of food administered to the stomach in a definite state (fasting) to be removed after a definite interval. Experience has shown the futility of expecting most patients to carry out these conditions precisely and it is far better to have the entire procedure supervised by the physician or his assistant. Handled in this way, the following information becomes available: The amount of contents recovered reveals the emptying time of the stomach. Simple chemical tests show the absence, or presence and amount, of acidity. Only the free hydrochloric acid and total acid figures are of clinical importance. Special tests for blood, bile, and lactic acid are generally unnecessary. The presence of the first two is sufficiently revealed by their color. Microscopic examination of anything but suspected tumor tissue is generally not helpful. On the other hand, the odor of the recovered material may be suggestive. Ordinarily, stomach contents are sweet, that is, they have the odor, if any, of the food as swallowed. Incidentally, it may be remarked that fetor *ex ore* is practically never fetor *e ventriculo*. Contents that smell sour, or as of stewed prunes, indicate retention. A foul or putrid smell speaks for malignancy, a fecal odor, for intestinal obstruction.

Special meals are used for estimating the emptying time of the stomach. The Leube meal consists of a small mixed dinner which should normally be evacuated at the end of seven hours. The difficulty with complicated meals is that they are hard to recover and that even a normal stomach requires a fairly long time for the evacuation of the most simple combinations. A much more practical procedure, on the other hand, is the employment of milk (say a pint of milk with or without two eggs beaten in it) as a motor meal. Such a meal is normally evacuated within about five hours and is easy to withdraw. These qualities make it available for a course of repeated observations—a method that is in every way to be preferred to a single test of this important function. In fact, employed in this manner, the procedure becomes of value not only for diagnosing the nature and prognosticating the course of a gastric retention, but, when combined with lavage, for the actual cure of the condition under observation.

Finally, a word as to the best time of day for gastric lavaging. When the stomach is washed at night, as is commonly done, the patient is robbed either of his food, if the procedure is done early, or of his sleep, if done late. By waiting until the morning, on the other hand, the residue of at least three meals is allowed to accumulate and a restless night is invited. It would follow therefore that the best time for the removal of residues and for lavages is just before dinner in the evening. In this way the stomach is not only put in the best condition for the reception and digestion of a heavy meal, but it is given the longest interval in which to do it.

Roentgen Study.—The Roentgen method offers perhaps more information than any other single *laboratory* measure. Both fluoroscopy and radiography should be used together and the patient should be examined in both the standing and reclining postures. It is of course impossible in a survey of this nature to do anything like justice to this aspect of our subject, but a few outstanding points ought not to be omitted. In the first place, the Roentgen method is the method par excellence for the establishment of the exact size, shape and position of the hollow viscera of the digestive tract. As a result, the clumsier methods heretofore in vogue, such as soundings, distention with gas, percussion, and palpation, have been largely supplanted. In the second place, by no other method can we learn so much concerning the exact tonic state of the hollow viscera. The peristolic function of the stomach is a term used by Stiller to denote the ability of the stomach to hold up its contents by the tonic action of its walls. This can be visualized only by the *x*-ray. The impairment of this function, the condition commonly called atony, is equally easy to recognize. Atony can also be suspected from the presence of gas ac-

cumulations, provided that obstructions can be ruled out.

As a means of examining motor functions, also, the Roentgen method gives accurate and comprehensive information. Very slight changes in the normal rate of food progress can be detected and gross obstructions are, as a rule, more easily studied by this than by any other method. Thus, in the case of the esophagus, the Roentgen method has practically superseded the use of bougies and the esophagoscope as a diagnostic agent. In general, it should be stated, however, that although the *fact* of disordered motility is very positively demonstrated by the *x*-ray, its *cause* may not be so clearly shown, and often requires further and independent study.

Occasionally, but rather less often, I believe, than is the general impression, direct evidence of actual lesions is available. Gallstones are about the only lesion that can be seen as such. The diagnosis of new growth, ulcers, and adhesions, is generally inferential. A few words as to cancer of the stomach. Undoubtedly the *x*-ray is the best modern means for diagnosing this condition, and it should never be neglected in cases of dyspepsia occurring past middle life. Cancers of the mid-region of the stomach can be diagnosed readily when filling defects are produced. Cancers at the pylorus cannot often be distinguished from other obstruction-producing causes. Cancer of the cardiac region, unfortunately, is very hard to visualize and is often overlooked. There is a type of cancer, infrequent to be sure, which can be diagnosed readily, and often only, by the *x*-ray, and that is the scirrhus cancer with the associated high, shrunken, clinically impalpable stomach.

Ulcers are not so readily diagnosed as the laity, at least, seems to think. It is the exception, rather than the rule, to find a niche on the lesser curvature or a persistent deformity of the duodenal cap. The syndrome of hypertonus, hyperperistalsis, and initial hypermotility with or without a six hour residue, spells duodenal or pyloric irritation which may originate from stomach, gall bladder, appendix, or bowel. The differentiation depends on other than Roentgen data.

As regards appendicitis, in the acute condition, *x*-ray is out of the question. In recurrent or chronic cases fluoroscopy may reveal localized tenderness and adhesions. If the appendix is filled, still more data are available, such as the position and shape of the organ and whether it is adherent or free.

In the large intestine, such conditions as constipation, adhesions, and obstructions are the chief subjects of study. No examination of the colon is really complete without studying the filling both by mouth and rectum. The barium enema should always be administered under fluoroscopic control, and in general, fluoroscopy of the bowel is even more important, if possible, than that of any other portion of the digestive tract.

In presenting the above sketchy outline, the writer has endeavored to offer a plan of procedure that has worked well in private, dispensary, and army hospital practice. A summary of this sort undoubtedly leaves much to be desired. Yet the progress of gastroenterology is nowadays so rapid that a survey from time to time of the whole field, clinical as well as laboratory, may find a place and perhaps be of value to all of us. It is in this spirit that these lines have been written.

44 WEST 96TH STREET.

MONAKOW'S VIEWS ON CEREBRAL LOCALIZATION.*

BY JOSEPH SMITH, M.D.,

NEW YORK.

PSYCHIATRIST MENTAL HYGIENE CLINIC FREE SYNAGOGUE; NEUROLOGIST O. P. D. JEWISH HOSPITAL, BROOKLYN; FORMERLY SENIOR ASSISTANT PHYSICIAN, BROOKLYN STATE HOSPITAL.

THE problem of cerebral localization has occupied the attention of physiologists for more than half a century and the names of Hitzig, Goltz, Munk, Jackson, Broca, Wernicke, and Charcot are indissolubly connected with it. Experiments on lower animals and observation of diseased conditions in man have greatly enriched our knowledge concerning this subject. By these means physiologists have mapped out in the cortex a visual area, an auditory area, and areas for motor and sensory representation. When, however, we inquire what is actually localized in these areas we must admit that we know very little about it and we can form no adequate conception of what we mean by cerebral activity. The current conception of the visual area in the occipital lobe, that it represents optical ideas, or representations; of the auditory area, that it is the storage of auditory impressions; of Broca's convolution, that it is the center for speech; of the frontal lobes, that they represent intelligence, must, in the light of our present-day knowledge, be discarded. The fault with these conceptions lies in the confounding of two dissimilar viewpoints—namely, the anatomicophysiological and the psychological. When we speak of seeing, hearing, motion, etc., we use psychological terms which have a definite unified meaning, representing as they do simple and unified acts. Physiologically considered, however, they represent complicated processes made up of many components, differently organized in relation to time. In the current psychological conceptions of these terms we easily overlook that apparently the simplest sensory perceptions of the adult have an enormously complicated phylogenetic and ontogenetic developmental history and contain a number of functional elements which are not taken account of in the habitual psychological use of the terms. Clearly, our first aim should be to study our sensations and motions in their component parts before they are brought together into circumscribed cortical areas. And what is here said of sensation and motion should apply with even greater force to highly specialized functions, as when we speak of ideas and intellect.

The fully developed human brain is the end-product of a complicated phylogenetic and ontogenetic evolution extending over centuries and neither its structure nor its functions can be readily understood without reference to its various developmental phases. The most primitive nervous system (*Lumbricus*) is represented by a few sensory and

*Read by invitation before the Queens County Medical Society, March 15, 1920.

ganglionic cells which are brought into relation with each other and with the muscular apparatus and other organs by means of nerve fibers.

The first differentiation of the central nervous system comes from the splitting off of certain ectodermic cells, and the further development consists in greater refinement of the sensory organs serving the better adaptation in the struggle for existence. The phylogenetically young cells develop out of the old and there results a constant shifting of positions of the newly acquired structures cephalad while at the same time they undergo typical changes in organization until they reach the stage of five subdivisions in the higher vertebrata. The earliest organization of the central nervous system consists of a pair of ganglionic masses which are connected with individual organs (molluscs, insects). In the vertebrates this ganglionic system has developed into the metameric system. Even here we find the rudiments of a brain-stem in the form of a thickened knoblike upper extremity of the spinal cord. In the fishes the differentiation is still higher—here we have 5 distinct parts of the brain—the forebrain consisting mainly of the organ of smell. At this stage of development, the roof of the midbrain exhibits an accumulation of cells. It contains the cells for the mechanism of sight, also for whatever psychic activity that being is capable of. In the next higher stage (amphibia, reptiles, etc.) we find definite purposeful combined movements while at the same time there is a further development of the sense organs, leading to perception of hearing, recognition of colors, etc. Alongside of this functional development there is not only a relative increase of the brain, but there is virtually a new central nervous system—to the metameric and midbrain systems are added the system of the cerebrum with its cortical evolution in the neighborhood of the cornu ammonis, also visual and motor areas. This cortical organization and the later developed projection system take over the somatic functions, leaving to the ganglionic, metameric, and midbrain systems the exercise of their former functions. In the highest developed mammalia the nervous functions are expressed more in the direction of individual experiences and of purposeful activity. Such functional increment is accompanied by the development of cortical association areas.

The phylogenetic wandering of a function cephalad can be best shown in the optic tracts and centers. Originally the sense of sight served principally the purpose of orientation in space and the protection of the body. The finer differentiation of the retinal images enabling the creature to distinguish qualities of light and forms was later added in the interests of food acquisition. Even at this low developmental stage the optic apparatus stands in close relationship not only to the mechanism for the eye movements, but to other parts of the body, which serve the animal to orient itself in space. And here we observe that the centers for eye movements which originally, together with the optic centers, were exclusively localized in the midbrain, in their wandering cephalad, were also drawn into the cerebral cortex when such change became necessary in the interest of space orientation. In the cortex they now occupy a position near the optic centers and are so arranged that the turning and fixation of the eyes are exactly and promptly carried out. These new cortical representations of the retina and their corresponding eye movements are closely bound up with local representations of other senses and their muscular mechanisms, which are nothing but reactions to light and skin irritation by appropriate muscular movements. All these centers form a diffusely spread but closed reflex arc, and the sum total of their activities forms the basis for spatial concepts. The migration of the primary optic centers to the occipital cortex and the transition of the midbrain sight to the occipital sight, takes place in the following manner: The cells of the outer geniculate body as well as those which later develop into the optic cortex become detached from the mother-center in the midbrain (fishes), the lateral geniculate body becomes organized into the midbrain and the optical cortex into the occipital lobe, without, however, their severing connections among themselves and with the old optic centers. The cortical optical centers and the cortical centers for eye movements develop together and form the basis for the future higher optical qualities.

Although the phylogenetic and ontogenetic investigations have brought us a better understanding of the gradual development of nervous functions, we are still far from knowing how the numerous connections which are necessary for nerve activity take place. Brain anatomy shows us the connections of the nervous system by means of afferent and efferent fibers, it touches the spatial relations only; but functions have their time as well as space relations, and the more highly organized a function is the greater the time relation becomes. The most important elementary properties of gray matter, Monakow summarizes as follows: (1) The instinct of self-preservation and preservation of the species. (2) The ability to react to external stimuli. (3) The ability to retain impressions—memory. (4) The property of passing into a state of exhaustion following severe exertion and to pass into a condition of shock as a result of severe injury. (5) The property to progressive development and attainment of perfection, by forming new points of contact and new centers of activity.

These properties of the gray matter are very important as they form the basis on which localization of functions may become possible. For the present, however, very little that is definite is known concerning localization. True, anatomical and physiological investigations have greatly enriched our knowledge of localization, but when attempt is made to use scientifically the accumulated knowledge, we at once get into difficulties. When the first experimental observations have shown that injury to definite cortical areas results in disturbances not only of sensation but of higher functions (gnostic, speech, writing, etc.), it appeared then to many as quite evident that in each so-called corticosomatic area not only common sensibility and kinetic impressions are present, but also ideas and representations (optical, acoustic, sensational, etc.), and that each cortical area contains specific sense representations. We began to speak of centers for optical ideas, ideas of movements, speech memories, etc., and the loss of such faculties was ascribed to focal lesions in definite convolutions, etc. Evidence, how-

ever, has gradually been accumulated, especially in recent years, both clinical and physiological, which did not agree with this center theory. It was observed that the symptoms resulting from a definite cortical lesion are more complicated in character than those adherents of the center-theory ever assumed, and in the evaluation of the symptoms not only the seat of the lesion but the time—moment, the duration of the lesion—plays a great rôle. Of course, all authors admitted a certain bodily and sensory representation in the cortex, but which special components of the sensory activity or which higher factors are represented in each cortical sensory area, about this no definite statement could be made. What, however, was especially damaging to the functional theory is the experience that the symptoms following destruction of definite motor or sensory areas frequently disappear rapidly. The loss of function resulting from experimental procedures on lower animals is quickly recovered from even when the extent of the lesion corresponds to the definite sense area mapped out by investigators. The symptoms that remain more or less permanent, especially in bilateral lesions of the cortex, are generally of rudimentary character. What really is lost are certain components of a function but not the function as a whole. Moreover, it was also demonstrated that destruction of definite deep-lying structures (for instance unilateral midbrain lesions or removal of one lobe of the cerebellum) is followed at first by a number of serious disturbances, the majority of which are recovered from, a few, however, remaining permanent. At any rate, the assumption that lesions of definite brain areas result in loss of "ideas" is a highly artificial conception. After destruction of definite areas in the brain, the symptoms may be either of a permanent character, directly resulting from the anatomical lesion, or they may be of a temporary character. The temporary symptoms as a rule accompany the permanent symptoms, they disappear after a variable length of time, depending upon the seat and extent of the lesion and whether the tissue affected was healthy or already the seat of disease. The permanent symptoms are as a rule relatively coarse—total or partial hemiplegia, loss or reflexes or of coordination, hemianopsia, etc., and the study of these permanent defects has been most helpful in giving us an insight into the structure of the nervous system and localization of functions.

How should we explain the temporary symptoms? Their origin is admittedly dependent upon the focal lesion or circulatory disturbances (for instance, aphasias.) Agnostic disturbances are due to lesions of branches of the anterior or middle cerebral arteries, but a definite and regular relationship between the seat of the injury and the symptom-complex, as where the symptoms are permanent, does not exist. Most authors make no distinction between temporary and permanent symptoms as far as localization is concerned, others assume that they are the result of inflammatory conditions. The current explanation of the gradual restoration of function notwithstanding the persistence of the lesion (recovery from aphasic disorders for example) is that the unaffected part in the neighborhood of the lesion or the corresponding area in the opposite hemisphere assumes a vicarious function. Monakow is strongly opposed to this substitution hypothesis. He argues that the building up of a new function in an area originally foreign to it is highly improbable. Many such functions are of high order requiring years of exercise for their full development (for instance, speech). Such functions of a highly specialized order may return in a very short time after the destruction of their hypothetical centers. Furthermore, the assumption of such functions as speech, sight or praxia has been relegated to convolutions which are not infrequently themselves the seat of disease or exhaustion. When, in addition, it is remembered that return of function is frequently complete, while it must be assumed that every newly acquired function must of necessity be at the expense of the centers which originally were endowed with this function, it will become apparent that the substitution or vicarious hypothesis has no basis for its support. Monakow here advances his own hypothesis—the restoration of function is due to gradual resumption of activity on the part of an area which was temporarily in a state of passive blocking, because of its connection with the seat of the lesion by means of nerve fibers. This conception leads us to his theory of shock. He classifies shock as follows:

1. *Psychic shock* brought about by powerful emotions, fear, etc. Here are included hysterical paralyses, hysterical blindness, etc. It is probable that the sympathetic system is here involved.

2. *Surgical shock,* or surgical stupor, brought about by severe injuries of bodily organs, skin, or nerves.

3. The shock-like state due to brain concussion or loss of continuity of brain tissue, hemorrhages, etc.

4. To these three forms of shock, Monakow adds a fourth which he names *diaschisis*—splitting of function through loss of one of its directing parts (local shock). Diaschisis also results from severe brain injuries, but the area affected is more nearly circumscribed; its spread is along definite channels. Clinically, the symptomatology varies, depending upon the fibers injured, whether these lead to the periphery or to the opposite hemisphere or serve purposes of association; so we have diaschisis, cerebro-spinalis, diaschisis commissuralis, associative diaschisis, etc. The diaschisis can be of brief duration, become permanent, or pass into the apoplectic shock and produce death. As an example of diaschisis without any anatomical change may be mentioned the loss of pupillary and patellar reflexes after an epileptic attack, or temporary loss of speech after head injuries. Where, therefore, we have before us temporary symptoms, not explainable on pathological grounds, but in close association with a definite lesion, and especially where there is a rapid restitution of function highly specialized, we must assume not a vicarious process or newly developed functions, but the setting free of nervous elements from a condition of diaschisis. That the problem of localization of functions becomes more involved as we proceed is now quite evident.

In the present stage of our knowledge, we can

speak of localization only in a general sense, keeping in mind possibilities rather than actualities. We must bear in mind that even the simplest nervous acts are complicated phenomena and that we cannot speak of localization *in toto*, but only of localization of the component parts. We should consider localization of sense impressions, of various forms of movements, of sense qualities, of time relations, synchronous or successive localization; there is the problem of the mneme—our memories. The principles of localization can be also applied to the consideration of various instincts. Experiment and clinical observation have shown that any cerebral convolution may be removed without affecting the feelings; pain, desire, fear, joy, anger, etc., even in the absence of the cerebrum, still remain, though in a much diminished quantity. We must assume that each cortical area is furnished with such feelings, so that after destruction of a large part of the visual cortex pleasurable and painful sensations from the retina, and after destruction of the temporal cortex in sensory aphasia, these same sensations are no longer appreciated. This occurs even then when the part of the cortex remaining sound is so large that its functioning is not interfered with and the corresponding sensory stimuli are still appreciated. Soul-blind people are notoriously indifferent to optical impressions, and word-deaf people to sound impressions.

The best known localized areas are those of the corticosomatic system. In complicated activity the whole nervous system is involved. In locomotion, for instance, the metameric system (spinal cord) furnishes the control of the successive steps; the cerebellar system, the factors for correct posture, equilibrium in station and motion and the unconscious finer movements; the midbrain holds the balance of the various metameric parts together, that is, it coordinates their activities; while the brain undertakes the regulation of impulses, the guidance of the whole, the orientation in space, furnishes the mental component of the locomotion, and finally determines the purpose of the whole complex activity. Of all cortical areas the best known is the visual area in the occipital lobe. Even here we cannot speak of centers for complete sight, or visual images in a psychologic sense. Such do not exist. What is localized there is the mechanism whereby the eyes turn in the direction of the source of light. On the other hand we know little about the order, organization, and extent of those paths in the cortex which lead directly to the macula lutea which is the place of conscious vision. We do know, however, that an individual may be deprived of both his visual cortical areas, may go about like a blind man, unable to orient himself in space, in whom light from any part of the retina no longer produce movements of the eyes in the direction of the source of light, and yet may not only have sensations of light (from some unknown cortical area) but can even read print. In short, according to our present knowledge we must sharply differentiate vision serving orientation from mental grasp of the seen—cognitive seeing. The same may be said of cortical area for hearing; the loss of both temporal lobes by softening does not preclude understanding of spoken language.

What should we say about the localization of higher functions, of conscious orientation in the gnostic sense, of symbols and language signs, praxia and apperception? To answer these questions, we must again return to the origin of nervous functions in their earliest stages of development. Here we find that higher functions develop out of lower and the lowest are reducible in the last analysis to the elementary sensations and reflexes and these are depended on the neurons in the various systems. The actions and interactions of these systems and the conversion of potential into actual stimuli and vice versa furnish the basis for the future development of the higher functions, engram-complexes, as Semon termed them, by which we understand ideas, perception, memories, etc. These spread out beyond the confines of the cortical somatic areas and become so to say the property of the whole brain. And a differentiation of these engram-complexes is possible only in the sense of chronological cortical strata—in other words, along the lines of the development of these functions, some of which become apparent only through diaschisis, after focal lesions, as fragments of remaining functions.

Viewed at from this angle, localization is seen as subject to constant change and embraces all the numerous developmental phases which we can only roughly and schematically reconstruct on the basis of our phylogenetic and ontogenetic studies. We are not justified to confine within strict limits, to bound by geometrical lines nervous activity, even of the simplest kind. Each cortical area or stratum will have a fairly definite physiological role assigned to it, but in each there will also be unknown components of other functions—we can speak here of a multiplicity of centers. There are undoubtedly performances with an anatomical localization which is relatively circumscribed; these are in the first instance the reflexes and reflex actions. Even here we must note that for the organization and realization of even the simplest reflexes, several systems of neurons are invoked, namely ganglionic, metameric, midbrain, and cortical systems and that they all combine to produce the reflex, so that we have here a *polymorphous representation*. What is especially interesting is that the cortex plays a definite rôle in the reflexes (and contributes a very important component of it, for instance in the plantar reflex, so that in certain localized destructions of the cortex the reflexes become split) due to loss of the cortical component. Such splitting is at times permanent; no substitution is possible. The reflexes form the basis for the other nervous functions since the more complicated nervous activities differ from the reflexes mainly through the increasing complexity of their chronological structure. The more complicated a nervous activity is, the more complicated the coordination of its parts are, the greater the number of polymorphous components that take part in the realization of an act, the greater is the extent of the brain surface over which the "function" spreads out. Yet, in lesions, it is possible here to isolate artificially certain somatic and sensory components. In the highest functions, which differ from lower functions more in their relations of time than locality and which have developed gradually, where memory plays a prominent rôle we can speak only of localization in the sense of development or de-

generation, that is a constantly changing localization. Monakow concludes that his theory of diaschisis, in conjunction with other forms of shock, forms the connecting link uniting the nervous functions capable of localization with those incapable of it. The diaschisis is nothing else but a temporary break in the activity of the highest functions. It engenders a struggle for the maintenance of the life of the function. This struggle has its counterpart in the constant conflict of the normal nervous impulses of our daily life. And, fundamentally considered, every nervous function is the result of a struggle which the various central systems, since the beginning of their phylogenetic development, have carried on and are still carrying on among themselves and with the outer world.

216 East Fifteenth Street.

STAMMERING, AS IT IS.

By ERNEST TOMPKINS, M.E.,
PASADENA, CAL.

Four years ago Fletcher wrote in regard to stammering, "The sufferers from this affliction have looked to the medical profession for relief since the existence of that profession and have looked in vain. While medicine has made almost unexampled progress in the understanding and treatment of known diseases, and has added to the list of those that were formerly unknown, regarding this old, old malady, whose record dates back at least to the Egyptian hieroglyphics, there is in the medical world of to-day little more than a confusion of personal opinions and theories. . . . This subject is of sufficient importance to deserve better treatment."[1] This arraignment of Fletcher's, although it fails to give the profession credit for Dr. Liebmann's work, is not overdrawn in respect to the confusion; and it is as true to-day as it was four years ago. Those who have real regard for humanity and science and the medical profession will endeavor to reduce that confusion.

Before we can reduce the confusion we must realize the causes of it, and a little reading of the subject will show one cause to be mixed truth and error. Take a current example. Not long ago Dr. Kenyon made two contributions to the subject, a rather elaborate thesis[2] and a short article.[3] These are valuable in that they show the habit nature of the disorder, even in its details; but their value is largely nullified in that they pronounce the disorder to be developmental. Rectification was of course necessary. Dr. Swift attempted it.[4] He properly shows the invalidity of the developmental allegation, but he denies the emotion of stammering. In short, he corrects one error but sets up a more serious error. Now what chance is there of getting the truth when every move in that direction is saturated with error?

In Dr. Martin's article entitled "Stammering," published in the Medical Record of May 29, 1920, although the proportion of truth is large, still there is a modicum of error. Let us endeavor to make it all truth. And let us further endeavor to make the truth convincing. If that article can be revised from what it contains and can be made thoroughly consistent, then the reader ought to be convinced that the revision is reliable and instead of accepting it on the authority basis with necessary reservations, he can accept it on the reason basis with dependability.

Dr. Martin tells us the nature of the disorder, and with slight interpretation of his account we may obtain a clear conception of it. He says: "A patient may, for instance, try to say 'mother' with his mouth wide open—an impossible position for the letter 'm,' which requires the lips pressed together. The indellible impression made upon the mind of the stammerer by his effort to speak, increases the physiological cause of his suffering. When laboring under the compulsive idea that he is unable to articulate normally there is an undue amount of nerve energy released by his brain in the attempt to control the organs of speech. The muscles laboring under this excessive innervation become rigid, jammed together, and a general juxtaposition results."

Now in the interpretation of Dr. Martin's descriptions, in order to be backed by high medical authority and to avoid suspicion of bias, I will, for the general interpretation, quote Dr. Liebmann's words regarding the stammerer: "If he has to speak, he becomes excited and makes voluntary efforts intended to bring out the 'difficult' sound, but which really obstruct it."[5]

Before we take up the special interpretation it is advisable to bear in mind that normal speech is automatic and that the stammerer's efforts are voluntary. Credit for this distinction is also largely due to Dr. Liebmann.

When the stammering child wants to say "mother" it remembers the humiliation of past failures in uttering that sound. It has been laughed at or reproved. In order to avoid further humiliation it makes a conscious effort to say the word, but no one knows how he talks, so the effort is misdirected. In this case the child probably reasons, "I must open my mouth in order to say the word," and it opens its mouth too soon, thereby obstructing its normal speech. For this failure it is further humiliated, and this humiliation goes to increase its dread of speech difficulty and its determination to make more effort to talk. The habit is self-intensifying to an appalling degree. One point more is necessary. How does it begin? It begins by a temporary interruption to normal speech. There is no question about this in the cases acquired by imitation. The imitator consciously impedes his normal speech and no serious consequences follow until the fear arises. Some one tells him he is likely to catch it or he remembers an imitator who has caught it or in some other way he is induced to make a voluntary effort to avoid catching it. That fright-impelled effort is misdirected and obstructs normal speech. Somebody laughs or mocks and the chain of misery is begun, probably to end only in the grave, not infrequently self-sought; and in spite of anywhere from half-a-million to a million such cases in the country, the score or more of writers on the subject please themselves by juggling personal opinions that keep up the confusion and its consequent appalling misery. Accidents and incidents also cause the temporary interruption which induces the disorder. A fall, a sickness, a fright will temporarily incapacitate normal speech and then the conscious effort is begun.

If the above conception of stammering is valid it will harmonize all features of Dr. Martin's discussion, sustaining the truths and amending the errors, and the discussion itself will justify the conception, warranting its acceptance by the reader. One thing should be kept in mind, namely, that although the origin of stammering is largely an unavoidable consequence of the peculiarities of the speech faculty, the continuance of stammering is an avoidable consequence of the cruelty of the human race. The stammerer would recover if society did not drive him deeper and deeper into his misery. Society humiliates him if he does not do as normal talkers do: if he does not answer questions, telephone, dictate, introduce friends, exchange greetings—in short, if he does not conform with speech conventions which are made for normal talkers but are inimical to him. He is discharged from work or given inferior work, he is considered queer, he is ridiculed or scorned. In order to avoid this injustice he continues his efforts to talk, not realizing that they constitute the actual trouble; and so he is forced into his impediment, for every convulsive effort induces more and worse efforts.

Possibly one more point will help to a clearer understanding of the disorder, and consequently of Dr. Martin's discussion, and that is the recovery. Notice the word "recovery"—not cure. As we have shown, the stammerer interrupts his normal speech; so necessarily he has normal speech, else he could not interrupt it. Moreover, he uses his normal speech when he is not embarrassed. Most stammerers do far more normal talking than they do stammering. The stammerers who approach muteness are almost invariably those unfortunates whose impediment has been intensified by the prevailing treatments. But every stammerer does some normal talking; and this is the means of recovery, for it instills confidence of speech ability just as the stammering instills doubt of speech ability. The recovery of the girls, a fact as obtrusive as it is avoided, is an illustration of this recovery. Their environment facilitates normal speech and discourages indulgence in stammering; so the fear of speech difficulty wanes to disappearance and normal speech then prevails. A considerable proportion of male stammerers recover by the same means. Roughly, the time necessary for recovery is proportional to the extent of indulgence in the stammering. A child who has stammered for only a few days will recover quickly if it is not allowed to stammer, but a man who has stammered for most of his life will not entirely recover for several years. He may, of course, be brought to fluency by an artificial environment in which he is relieved of speech responsibility, but years of that fluency are necessary to dissipate totally the memories of past failures.

Now let us take up the statements of Dr. Martin which agree with this conception of stammering taken from his own description.

"Ignorance of this subject is appalling among those who have the care of children." This is perfectly true, and it is also true of most of those who attempt to instruct those who have the care of children. A medical friend whom I interested in the subject set himself to learn about it by reading the medical literature on the subject, and he wrote me that he was perfectly confused by it. That result was practically inevitable, as may be realized from the fact that the three popular theories of the subject, namely, "transient auditory amnesia," "visual asthenia," and Freudianism are each and all fallacions, yet a considerable proportion of the current contributions to the subject are expositions or variations of these theories. The public is not to blame for its ignorance of the subject. The blame rests with those who disseminate the misinformation.

"Physical obstructions of the air passages seldom bear a direct relation to stammering. They may, perhaps, be causal agents through interference with clear enunciation or perfect articulation, but cannot be considered a cause *per se*." This is a clear view in face of the fact that a great proportion of the discussions are to the contrary. Dr. Makuen was a firm believer that nose and throat affections had an etiological relation to stammering, and it was only shortly before his death that he came to the conclusion that "stammering is a psychical rather than a physical disorder." We can readily see that Dr. Martin might have gone further and said that physical obstruction of the air passages has no relation to the disorder. Since the continuing cause is the fear of speech difficulty, the obstruction could not be, or contribute to, the continuing cause; so, if it had any causal relation, it could only be as an inducing cause. But there is no apparent way in which obstructed—partially obstructed—air passages could induce the conscious, misdirected effort at speech. A stammerer may have catarrh. Many stammerers do. But no relation between the two affections has ever been shown, and the nature of the disorder indicates that there is no relation; so it is wrong to allege one.

"Nor does nervousness cause stammering, as commonly supposed." Here, again, Dr. Martin is right, and the subject is important. Although the popular theories hold the field by reason of their novelty, the great resort as a cause of stammering is nervousness. For lack of a known cause it holds the place in stammering that "heart failure" does in mortality; and it is pleasing to hear an authority speak against it. Most stammerers are nervous. They are pestered beyond the comprehension of a normal speaking person. They are almost never free from planning and scheming to express themselves without stammering. They arrange and rearrange their comings and goings to that end. They construct and reconstruct their conversation, keeping in mind sets of remarks for each expected contingency. But every contingency cannot be foreseen, and, in spite of the prodigious mental effort, stammering is unavoidable. The wretched victim of misapplied convention blushes, sweats, writhes, and inwardly curses the fate that blights almost every feature of his life. Nervous? Yes. Who would not be nervous under the circumstances? But the nervousness is resultant, not causal.

"A common fallacy in attempting to correct a case is to ask the stammerer to take a breath before speaking each word or group of words. The

fact that he is made to realize that he must take a breath recalls to his mind his inability to speak as others do. He even recalls the mental pictures of his past suffering and fear predominates to such a degree that all the coordination of nerves controlling speech is temporarily destroyed." This is such a good account of the effect of breathing exercises, namely to intensify the stammering, that one hesitates to correct any portion of it. However, the nerve coordination is not destroyed any more than the coordination of one's optical nerves is destroyed if the sight is obstructed by holding the hand over the eyes. The sight is blocked, but there is no upset in the visual mechanism. And that is true of stammering. The speech mechanism is in perfect order, ready to run, but the voluntary effort blocks the running. Anyone can prove that for himself. Let him hold his mouth open or shut and try to talk at the same time. He will to all appearances be stammering, but his nerves and his cerebrum are in perfect order, as he will find if he desists from the obstructive effort and allows his speech to operate. The grand mistake that practically all the investigators make is to translate the struggle from the peripheral organs to the central organs. Why not see things as they are? Indeed, any but a blind man can see the peripheral struggle, and many investigators—Denhardt among them—show photographs of the contorted muscles. Now be content with that, for a scientific deduction is merely a comprehensible description. But to change the facts and allege an internal struggle is the reverse of science—it is superstition. No valid evidence of an internal struggle has ever been presented, and the disorder is fully accounted for by the external struggle, of course taken in connection with the impelling fright.

Let us return to the breathing exercises. In pre-war days when every German practice was considered worthy of emulation merely from the fact that it was German, the breathing exercises were considered to be the most important feature of practically every treatment. Specialists and would-be specialists were determined to force the German system of treating stammering into our schools, and in some cases they succeeded. However, Dr. Martin tells us, and tells us truly, that the breathing exercises inculcate stammering. Consider, then, that stammering children in the public schools are being forced deeper into their affliction by treatments advertised to be beneficial but really intensifiers of the disorder. Read the reports of these treatments forced on the stammerers and you will find the breathing exercises still extensively used. But how can they be reported beneficial? For the simple reason that any distraction is a temporary reliever of stammering, and the exercises when new, and especially when practised in a non-embarrassing environment, afford a distraction which brings about temporary fluency, generally advertised as cure. In reality, in the child's natural environment, its efforts to breathe as it is taught, keep its difficulty in mind and thereby increase it. Credit to Dr. Martin for showing the mistake of this treatment and credit to Dr. Liebmann, who since twenty years ago has been a voice crying in the wilderness against it.

Now let us take up the features in which Dr. Martin's article fails to agree with his description of stammering. He says, "It is difficult to discover any cogent reason for stammering, for the original causes may be remote, having left only the effect." That seems to indicate failure to grasp his own description completely. What is difficult about it? A boy cultivates the habit of interfering with his normal speech, and fearing to contract the disorder, persists in interfering, not realizing that he is blocking his speech with every voluntary effort. Each effort increases his impression of speech disability, so the disorder grows on him. The course of events is perfectly logical and perfectly in accord with the observed and frequently recorded facts. Stammering is no longer a mystery.

"In the correction of speech defects it must always be remembered that each case must be solved as a personal equation." This belief was formerly fairly extensive from the fact that no two stammerers feared the same group of sounds, but since the appearance of Freudianism we hear it proclaimed by nearly every authority. In fact, there is no real basis for it. The stammerer fears the sounds with which he has had trouble, and these have some tendency to become stereotyped, for he will make further effort to avoid difficulty with them and thereby will continue the difficulty. But the course of recovery is identical with every stammerer, namely to "cut out" the stammering and to cultivate the fluent talking.

"The teacher is kindest who makes him prove that he can speak—when she forces him to overcome the handicaps of the class room." This is refuted by almost universal testimony and by the nature of the disorder. Rudolf Denhardt's testimony is convincing. He says, "For many stammering children the entrance in school inaugurates a significant period in the development of their impediment in which spring up new and grave dangers. The increased demands which the lessons place on their speech, the apprehension of making an exposure of their impediment before their comrades and becoming a welcome prey to ridicule; the anxiety regarding the opinion of the teacher; the not always appropriate treatment of the stammerers by the teacher; the realization coming first on the school bench with full force, of reduction in grade through no fault of their own, below others of no more ability—all this combines to engender in the soul of the stammerer every feeling which contributes to the increase of his impediment."[10] Evidently Denhardt does not find the conventional school treatment the kindest thing to the stammerer, and Denhardt gives his reasons instead of making a dogmatic statement. Albert Gutzmann says, "The school conditions—or similar ones elsewhere—call out the feelings of anxiety and shame and the impediment wins the mastery over the individual."[11] H. Gutzmann says, "Anxiety in the presence of the teacher, shame in the presence of the school children increase the trouble extraordinarily, and that in a very short time."[11] Dr. Wile says "Under ordinary circumstances the very act of recitation increases and tends to protract the disability."[12] I could fill a page of the MEDICAL RECORD with such testimony

from records at hand, and am confident that I could fill a whole number with a little research. But what is the use of multiplying evidence of what is evident? We have already shown that the custom of forcing the stammerer to talk is responsible for the continuance of the disorder. If he was allowed to take his time or not to talk at all when tired, ill, or discouraged, the fluent periods would remove the fear of disability and he would recover. He is constantly scheming to avoid stammering, but society as constantly forces him into it. Here in our supposed-to-be enlightened and Christian land we are forcing three hundred thousand stammerers into lives of misery in our public schools, and although the Commissioner of Education has repeatedly had the fact brought to his attention, he declines to use his influence to stop it."

"In my treatments I use a series of vocal gymnastics which I have carefully developed. The faithful practice of these exercises will not only intensify the auditory images of the stammerer. . . ." In "auditory images" we find the "auditory amnesia theory" cropping up again. It is hydra-headed. Whether or not these exercises intensify the auditory image is immaterial. Stammering is independent of the auditory image. The big question is, "Are the vocal gymnastics beneficial?" Dr. Liebmann says they are injurious, and he eschewed them along with the breathing exercises years ago. What is the effect of the exercises? Dr. Martin tells us that they have the effect of "focusing the attention upon direct control of the muscles employed." But that is the stammerer's trouble—conscious effort at speech; and just what it is necessary to avoid. Dr. Martin recognizes such necessity for avoiding the breathing exercises, but he fails to see that it is equally true of the vocal exercises. Let us pause a minute and take a broad view of the situation.

Why were breathing exercises and vocal exercises ever used? For the simple reason that it was thought the stammerer needed to be taught how to breathe and how to talk; our predecessors thought that the stammerer was deficient in these two functions. What was the result? It was temporary improvement and generally ultimate intensification of the disorder. Oh, I know, for I went through it—many times. A few, whose environment is favorable, may progress to recovery, *in spite* of the treatments. The proportion of recoveries, and after years of time, is variously put at from 1 per cent. to 10 per cent. Of the many cures which I attended I do not know of one recovery at the cure, and I do know that most of the attendants continued to stammer worse than when they originally took the cure, and after repeated treatments. What is the situation now? It is that we are very slowly coming to realize—what was always evident—that the stammerer's breathing and speaking are all right when he ceases to interfere with them. Leave him alone and he talks to himself fluently, hypnotize him and tell him that he is an orator and he orates, elate him and he is fluent, enrage him to the extent that he forgets his idea of speech disability and he will express his feelings without a hitch. He knows how to breathe and to talk, and, what is more, he knows these things better than anyone can teach him. His trouble is that he interferes with his speech by conscious speech efforts, and the exercises encourage him to do it more so. It is much to Dr. Martin's credit that he has spoken up regarding the intensifying effect of the breathing exercises; but he has still another step to take, which is to put the vocal exercises in the same class.

In closing it might be well to outline what should be done with stammering. Certainly we should cease from intensifying it. The public schools are the big factor in the continuation of the disorder, not only by making the stammerer worse but by favoring the contagion. The stammering child should be allowed to write his recitations and should be forbidden to stammer on school property. This one reform would within a few decades extirpate the disorder, for even severe stammerers would recover during the ten years of schooling. However, a five-year intensive campaign for the extirpation of stammering shows such a reform to be unpopular. The cure is wanted. "Give us the cure." Let me outline that again." To begin with, except at the very inception of the disorder there is no recovery sufficiently quick to warrant the name cure. Tell me how to destroy memory of speech difficulty without deleterious results and I will tell you a quick cure for stammering—otherwise not. One who long walks the path of the stammerer has a long walk back—not necessarily as long as the walk in, for a favorable environment may produce fairly rapid results. The means of recovery is the reverse of the means of cultivation of the disorder. The fear of speech difficulty was built up of repeated speech failures, and that fear can be removed only by repeated speech successes, and, of course, by desistence from further failures. First, the environment which conduces to fluency must be provided. such as freedom from speech responsibility, from embarrassment, weariness, and anything of a depressing nature. Hygiene is beneficial in that it contributes to buoyancy, and that contributes to fluency. Every stammerer should always carry a pad and pencil and the determination to use them rather than stammer, for without the latter they are useless. He should have congenial company, preferably one companion at a time, and should be kept talking, fluently. At first his remarks will be short, for he can not say many words without remembering trouble with a coming one and making trouble when it arrives. Thereupon he should check himself, or be checked, and should do anything but stammer. He may "let it go," he may write it, he may use a synonym; but in any case he should avoid stammering. There is no valid reason why the institutions now treating stammering by methods which intensify the disorder should not treat it by this rational and beneficial method. The environment is there, and the associates are there, for two stammerers will often converse with comparative fluency on account of the bond of sympathy between them. Recovery will not ensue at the treatment unless the stammerer makes a long residence there. Apparent recovery, that is, complete fluency, may occur, just as it does with the present treatments; but the

underlying fear will still be there, just as it is with the present treatments, ready to spring into full strength with a few speech failures. Complete subjugation of it is possible only by consistent maintenance of the regimen. Dr. Kenyon is right in saying that real recovery must occur in the stammerer's natural environment.[15] He must learn to keep the fear in subjugation there before he is master of his speech. The temporary uplift and the proper course of procedure may be obtained at the treatment, but the ultimate recovery must be patiently worked out under the circumstances in which the stammerer lives.

THE TREATMENT OF GASTRIC ACHYLIA.

BY MILLS STURTEVANT, M.D.,

NEW YORK.

LECTURER IN MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

WHEN achylia gastrica is due to malignant disease of the stomach or elsewhere, the treatment is, of course, surgical. When achylia is due to gall-bladder disease, again the cause is treated. Of Lockwood's (1) 153 cases of achylia only four were malignant. Of the remaining 149, 33 were associated with gall-bladder disease. This leaves 116, over 75 per cent. to be accounted for by other means. In these remaining cases the causes are not clear-cut and definite. Suggestions that there is a local catarrh affecting the stomach glands, that there is a primary atrophy of the tubules, or that irritative or infective foci outside the stomach cause the condition, are attractive and plausible. They do not, however, indicate successful treatment aimed at the cause.

A number, possibly large, of individuals with gastric achylia present no symptoms and receive no treatment. It seems reasonable to think that in such people the pancreatic digestion compensates for the loss of gastric digestion. The treatment of patients with symptoms consists in making use of the pancreatic digestion, in restoring the reservoir action of the stomach with slow transference of small amounts of chyme to the duodenum and in taking such steps as are possible to restore to the stomach its normal secretion.

Diet.—The food prescribed must be bland so as not to aggravate or induce catarrh of the stomach. It must be selected of foods suitable for pancreatic digestion. It must be cooked properly and served in a finely divided condition. Meats must be so cooked that the connective tissue framework is softened and the sections of meat separate readily. Boiling and stewing are satisfactory methods of preparation. Roast lamb is physically better adapted for digestion than roast beef. Fried and broiled meats should not be allowed. Fish is suitable for the achylic dietary and is usually well borne. The vegetables allowed should be tender ones, such as can be passed through a purée sieve. Just how much of the subdivision of these foods can be done by the patient and how much should be done for him will vary in different cases. If the patient is able to chew his food well and will do so, he may be allowed to have his vegetables served whole and his meat without mincing. If however he has not sufficient teeth or his teeth cannot be put in proper condition, or he will not take the time and pains to masticate well, his vegetables should be puréed and his meat minced. It is often worth while to ask the patient if he is chewing his food thirty-two times to each mouthful and to explain again and again the advantages of so doing. Once established such a habit is of great value and not likely to be given up. Cereals should be well cooked. Salad and raw fruit should not be taken.

The following is the diet list used by the author. Directions may be added to the margins, and changes to suit the individual case are easily made.

(A) Diet.

Breakfast:

Orange juice, grapefruit juice or pineapple juice.
Oatmeal which has been cooked three hours or more, cream of wheat or hominy with salt or sugar, and cream.
One slice of lean bacon or one soft boiled or poached egg. Toast or rolls with butter.
Marmalade or strained jelly or honey.
Tea, coffee or cocoa.

Midmorning:

A glass of milk or buttermilk with three or four saltines or a glass of malted milk.

Luncheon:

Clear broth or cream soup.
Any fresh fish, boiled or baked.
Roast chicken, turkey or lamb, stewed beef or lamb. The meat should be very well cooked.
Potatoes in any form except fried. Any vegetable which can be put through a purée sieve.
Macaroni or spaghetti.
Any simple dessert as ice cream, custard, farina, blanc mange, corn starch pudding, tapioca pudding, baked apple with cream, prune soufflé, simple cake or pastry.

Midafternoon:

Anything on the midmorning list. Cream cheese sandwich, simple cake or toasted muffins with tea or milk.

Dinner:

Anything on the luncheon list.
Olives, caviar, anchovy or sardines.
Bread and butter. Any cheese.

General Medical Treatment.—The amount of gastric juice secreted in twenty-four hours has been estimated at three pints (2). Carlson (3)

found 700 mils: secreted in four hours after a meal of meat, bread, vegetables, coffee and dessert. It is difficult to understand how twenty drops of a 10 per cent. solution of hydrochloric acid three times a day can have much effect on the digestion of an individual's food when his own hydrochloric acid is absent. However, many cases are relieved at once by such a dose, remain so relieved as long as it is taken, and soon have their symptoms again when the acid is stopped. On the other hand, hydrochloric acid sometimes gives no relief whatever. It seems probable that where symptoms are helped or stopped altogether, the hydrochloric acid acts by one or both of two means: It may stimulate or help to stimulate the pancreatic secretion; it may restore the reservoir action of the stomach. For when acid chyme is passed into the duodenum, the pylorus closes reflexly and remains so closed until that acid is neutralized by the pancreatic secretion. So that the chyme in the stomach passes little by little into the duodenum rather than overwhelming it with large units which cannot be properly acted on in the duodenum by the pancreatic juice. The hydrochloric acid may be given, twenty minims of the dilute in a glass of water to be drunk during the meal, or it may be flavored with syrup or tincture of lemon and sweetened with sugar.

That gastric secretion may be re-established should never be lost sight of. Meat extracts, of which there are several advertised and popular brands, are sometimes useful. A meat powder may be prepared by drying finely chopped lean beef over a water bath, scraping the residue into a mortar with a spatula and powdering. The powder is mixed, a teaspoonful or two to the cup of hot water. This is taken well seasoned with salt and pepper twice a day before meals. Meat, its extractives and powders, will increase acidity where the stomach is already manufacturing some acid. It will probably assist in re-establishing the acid of stomach juice where that acid is absent due to a suspension of the acid forming property of the gastric glands. Clear broth taken before luncheon and dinner serves the purpose nearly as well.

Drugs which directly stimulate the production of gastric juice are pilocarpine, choline and morphine. These are obviously unfitted for clinical use as Meyer and Gottlieb (4) have pointed out. Calcium salts and parathyroid gland are of no benefit.

Eyes.—Disease of the eye may cause functional stomach disorder. In 1894 Stockton (5) suggested that eye trouble, particularly astigmatism, might cause gastric achylia. It is well to have the eyes of the patient examined, and if astigmatic, corrected. Little can be promised from this procedure alone, however.

Mouth.—It is most important that the patient's mouth be put in as good condition as possible. The teeth should be examined by X-ray and a competent dentist should treat as indicated. Once in order, the teeth should not be neglected but should be examined at regular intervals. One part of the digestive sequence having been removed, the remaining parts must do extra work. An effective routine consists in brushing the teeth and washing the mouth the first thing in the morning with a solution of one-half vinegar and one-half water. After this the teeth should again be brushed and the mouth rinsed with a solution of a teaspoonful of bicarbonate of soda to the glass of water. At night a good dentifrice may be used. This procedure will usually relieve the bad taste in the mouth from which so many achylic patients complain.

Any focus of infection may contribute to the production of gastric achylia. The tonsils should be examined and if diseased should be treated or removed. Examination should be made of the antra and sinuses and inquiry made as to middle ear disease. The indicated treatment should, of course, be carried out.

Lungs.—Achylia is met with following acute infections. Recovery is usually spontaneous and rapid. It often accompanies chronic infections particularly tuberculosis and syphilis. It is well to carefully examine the patient for evidences of either of these diseases. If tuberculosis is present the achylia must be taken into consideration, and the institution of proper diet and other measures will often be of the greatest help in promoting nutrition and helping the tuberculosis.

Stomach.—The occasional patient will complain of an indefinite distress after eating. Sometimes it is described as "acidity" or "heartburn." Rarely there are "acid" eructations. It is sometimes difficult to convince patients that they have no acid in their gastric juice, so strong is their belief that they taste acid chyme. In these cases the small meals in midmorning and midafternoon are of great benefit, and should be prescribed as a routine, as they have the further virtue of reducing the bulk of the other three meals, which is an advantage where the reservoir function of the stomach is disturbed. Where it is impossible for the patient to arrange these small meals a glass of water will usually relieve the distress.

Intestines.—Diarrhea may be of two forms, that coming in the morning, leaving the patient free for the rest of the day, and another form coming in attacks without morning incidence, responding to treatment but recurring after a longer or shorter interval. With the morning diarrhea, the patient has ordinarily from one to four or more loose movements, coming before or after breakfast or both. This may occasion the patient no discomfort or may be accompanied by the rumbling of gas, a sense of distension in the abdomen, or even cramp-like pains. When coming in attacks it may be all grades from a few mild loose movements to severe seizures. In the former variety no special treatment directed to the intestines is necessary. It will be enough to prescribe diet, to give the hydrochloric acid, and to meet any other indications. In the latter if an attack of any severity has manifested itself, the patient should be put to bed. Over the whole abdomen a flannel wrung out in very hot water is placed and over this a layer of oiled silk. On the oiled silk should be placed a hot water bag lightly filled with very hot water or an electric heating pad. A high colon irrigation of normal saline, at 115° F. in the bag, should be given as soon as possible. The diet in severe cases should be limited to six ounces of peptonized milk every two hours. While in less severe or improving cases two hourly feedings of well cooked oatmeal or fine cereal, with milk or salt. Other foods which may be given are malted milk, dry milk, arrowroot gruel, milk toast or clear meat broth. As further improvement takes

place the various foods on the achylia diet may be given, first potatoes, then the desserts, then minced meats and last of all vegetables. For medication in severe cases it is well to start with a brisk purge. After this has acted ten minims of deodorized tincture of opium should be given and repeated every hour until there has been no movement of the bowels within the hour. Then it may be given after every movement though not oftener than once an hour. In the less severe cases or in severe cases as improvement begins, salol grains ten with castor oil minims ten in capsule may be given every two hours. The interval should be gradually lengthened as the patient improves.

Achylia may occur in the enteroptotic individual. In advanced cases splendid results are obtained by treating for three to six weeks in bed with achylia diet, hydrochloric acid and proper treatment for the ptosis.

Headache.—The treatment of this symptom is the treatment of the whole condition. Migraine which is due to achylia will usually be relieved by an achylia régime. If relief is not obtained by this means, causes of headache, other than achylia, should be suspected and investigated.

Blood.—Austin Flint (6) in 1860 pointed out the relations between profound anemia and atrophy of the gastric tubules. Primary idiopathic anemia is always accompanied by diminution or absence of hydrochloric acid in the stomach juice. In many cases of achylia there is a simple anemia of varying intensity. An examination of the patient's blood, including count of the red cells, estimation of the hemoglobin and examination of the stained smear, should be made in all cases of achylia, at least once a year. If anemia be present the patient should be given iron or iron and arsenic by mouth or by hypodermic injection.

Nervous System.—Achylia gastrica is sometimes spoken of as a neurosis and *achylia gastrica nervosa* has been used as a name for the condition. Any such conception of the disease is at best hazy and indefinite. Nor does the theory become more clear-cut by naming it sympatheticotonia or mixed vagotonia and sympatheticotonia. If it occurs as a result of nerve influence it seems likely that it is reflex from some trouble elsewhere in the abdomen, as gall-bladder disease or appendicitis, as Lockwood (7) has pointed out. On the other hand, some of these patients are neurotic. Such are benefited by three quarters of a grain of luminal three times a day after meals.

The occasional association of tabes dorsalis and achylia has been noted and a casual relationship suggested. Syphilis in any of its manifestations may be accompanied by achylia. Whether this is due to the disease itself or to the anemia which often accompanies this disease, treatment should be directed toward both.

Finally, estimation of the acidity should be attempted every six months for some years. The juice should be taken at short intervals over an hour and a half after an Ewald meal. A case has been reported where the acidity was reestablished after five years.

FIGHTING FIRE WITH FIRE.

BY GEORGE L. SERVOSS, M.D.,
RENO, NEV.
EDITOR, WESTERN MEDICAL TIMES.

EVERY now and then, and sometimes in the pages of the various medical journals, we read how the various cults, pathies, and so forth are making inroads into the practice of medicine and robbing the legitimate practitioners of their rights as physicians. We are also told that the quacks are successful, to some extent, in their work. We are also offered various sorts of remedies, but never are we told to fight fire with fire, for that would be unethical, you know.

The legitimate physician is *supposed* to sit in his office, very quietly, and wait for patients to come his way. He must not, by any manner of means, do any advertising. He must gain publicity only through his deeds, providing, of course, he has opportunity for any such things. That is, all this must occur, if the doctor be ethical.

On the other hand the cultist, pathist, or whatnot, advertises himself in one way or another and gains publicity at every turn, no matter what the means. A church may be the means in one instance, street corner talks in another, or printers' ink may be called upon. Without advertising or publicity, of one sort or another, the charlatan in medicine cannot live.

It is said that the quack usually "does something." On the other hand, it is said of the legitimate physician that he is not a man of action. He pays too much attention to the discovery of an ailment and insufficient to the bringing of his patient back to the normal. And there is some truth in that statement, for in this day of the laboratory we do become too greatly interested in diagnosis and very probably not sufficiently so in the matter of disease treatment. Therapeutics have gone too much out of style.

The charlatans claim many cures, but do not give credit to coincidence, for it is a known fact that many abnormalities will adjust themselves, even without a hand being taken by a cultist, pathist, or whatnot. Whenever a patient of theirs does recover his good health, Nature is rarely given much if any credit and we find the cultist or pathist or practor crying from the housetops, that all may hear, and that he may gain much publicity thereby, "I cured him!"

The legitimate physicians do not give themselves sufficient publicity. They do not fight fire with fire. The charlatans use the pages of their local papers, that their names may become household words. The legitimate profession may have signs

on their doors and windows, but to use printers' ink —that is a something not to be considered—not for an instant. For it is unethical, you know. Nor must the legitimate practitioner claim that he has cured a single patient, for he has never done anything of the sort. He has, perhaps, acquainted the patient with the name of his ailment, but further than doing that he must say nothing.

It has always seemed to us that every local paper should have printed therein a list of reputable physicians. We have much to say about medical practice acts as a protection to the public, but we do not advise that same public regarding who may be practising under the auspices of those acts. Supposing we offset the advertisements of the quacks with a list of the reputable physicians of a community, published without comment. That would be fighting fire with fire and would, without a doubt, attract many people from the doors of the charlatans. Supposing we went a step farther and, during an epidemic for instance, we gave publication to the public, through the medium of the secular press, those things which might act to make the cases of the disease fewer, then it might be that the public would think more of us, for we would be "doing something."

We are too prone to sit back and curse the illegal practitioners, but further than that we are inactive. We, in our endeavor to be scientific, become narrow minded and top heavy and finally we lose our balance and tip over backward. We lose sight of the patient and think only of his serum, of some one of his particular organs, and ignore him as a whole. We become so interested in the "scientific" end of things as to cease being doctors and become laboratory workers. We are so interested in knowing what ails a patient that we completely overlook the fact that he employed us to bring about a correction of his condition, be that "cure" or whatever name you may please to call it.

To fight fire with fire we should be just as active in our methods of treatment as are the cultists, pathists, practors, or whatever they may happen to be called. We must "do something" when a patient calls us in, other than perfect a diagnosis. We must take greater heed of the curative side of the question and we can, if we so desire, effect just as many cures as do the charlatans.

We have, at least some of us, ceased being doctors, in the true sense of the word, for we have ceased endeavoring to cure disease, or to make much of any effort in that direction. The average patient does not care a continental about some fancy name for his condition. What he is looking for is relief from that condition, and if he cannot get that relief through the ministrations of legitimate, educated, scientific physicians, then he is going to the quack, where, at the very least, something of a tangible nature will be done. The average layman does not care to what particular school a doctor belongs, just so long as that doctor obtains satisfactory results. You will find that irregulars, Christian scientists, and others of like sort all have their friends, and no matter how illiterate, in so far as medicine may be, those practitioners are.

First, in fighting fire with fire, let the doctors of community come from beneath the bushel and let the public be acquainted with their names, as legitimate practitioners of medicine. Second, let them "do something," other than make diagnoses, when called upon to give their services. Let them *really* give service to the extent of bringing about a resumption of the normal within the bodies of their patients, and that in the quickest possible time. Third, let the legitimate profession educate the public to the same extent as do the quacks. Finally, let the various medical practice acts be so rewritten as to close those loopholes which exist in every one now in force and which allow cultists, pathists, practors, and whatnot to carry on practice.

We realize that this is all very unethical, but it seems to use that we have been *too* ethical in times past. We have forever hidden our light under the bushel and have not claimed credit where credit was our due, excepting possibly in some medical journal, published far from our field of action, and never to be seen by our patients, the ones who should, very naturally, be interested in our activities and possibilities.

We may make vast claims as scientists, but we must be actors as well, for those who compete with us are actors, if nothing else. And it is because they are such that they wax strong and grow rich while many of we decent physicians become weaker and weaker and finally go to the pauper's grave, no matter what our attainments.

A little publicity, coupled with some ability, should be a good thing for the medical profession, as is publicity, associated with little or no ability, for the quacks. And the public would be better off because of the first mentioned sort, for they would have the assurance of the attention of educated men and women.

AN UNUSUAL CASE OF LATERAL SINUS THROMBOSIS.*

By JOSEPH FRIEDMAN, M.D.,

INSTRUCTOR OTO-LARNYGOLOGY POST-GRADUATE MEDICAL SCHOOL; ASSOCIATE ATTENDING BETH-MOSES AND BIKUR CHOLIM HOSPITALS; ASSISTANT ATTENDING WILLIAMSBURGH AND CONEY ISLAND HOSPITALS

AND

SAMUEL D. GREENFIELD, M.D.,

BROOKLYN, N. Y.

ASSISTANT ATTENDING OPHTHALMOLOGIST BETH-MOSES HOSPITAL.

LATERAL sinus thrombosis in most cases is a postoperative complication. Only rarely is the condition diagnosed or even suspected when the mastoid has not yet been opened. In the latter case it is most often apt to be associated with very virulent infections and in patients with greatly lowered resistance, or in those mastoids that have received improper care and attention and have been permitted to go on unoperated. The typical case of lateral sinus thrombosis presents a fairly distinct picture occasioning little difficulty in diagnosis. The patient who has been operated upon for an acute mastoiditis and who, several days later, has a chill followed by a sudden rise in temperature which then assumes a septic character, with remissions below normal, with a blood count of from 15,000 to 20,000 white blood cells and a differential count of from 70 per cent. to 85 per cent. polys, supplemented by a positive blood culture, offers no place for doubt in the surgeon's mind as to what he is dealing with.

*Read before a meeting of the Williamsburgh Medical Society, May, 1919.

Even in the absence of a positive blood culture, if pneumonia and erysipelas can positively be excluded, with a negative urine (especially in a child) he still has a fairly clear picture. This is particularly true if the operating surgeon recalls that at the time of operation the sinus plate was eroded and extensively diseased, or if upon exposure of the sinus granulations were visible over the sinus wall. The edema and swelling located over the so-called emissary region, the cord-like tender jugular in the neck with enlargement of the deep cervical glands, in a patient with pronounced euphoria, all aid materially in arriving at a definite conclusion. But it is an entirely different matter in the patient without these typical findings, especially those cases that occur in the course of an acute otitis, in which instance the symptoms, which are often severe during pus retention—fever, feeling of cold, pain and edema over the mastoid—may easily mask the symptoms of sinus thrombosis. Furthermore, there are cases of sinus thrombosis which run an irregular course with an irregular temperature, without chills and with only mild mastoid symptoms. The literature abounds with atypical cases of sinus thrombosis discovered at postmortem examinations, many of which have succumbed to the more serious complications following upon the unrecognized thromboses. There is no question that any otologist operating upon what he terms the "typical mastoid" would elicit surprise should he most unsuspectingly encounter a sinus thrombosis. Even greater would be his surprise if a patient had walked into his office on the same day, who, according to the mother, felt that he was not very ill, with a history that his present illness dated back only ten days.

The case we are recording is one in which we must confess that no diagnosis of sinus thrombosis was made, nor even suspected before operation. There were no symptoms nor signs at the time that led us to believe we were dealing with anything more than the usual "typical mastoid." The operation disclosed an infected thrombosis completely occluding the vessel lumen with a collection of pus in the sinus. The internal jugular was ligated but not resected. The patient made an uneventful recovery.

Report of Case.—Jacob T., aged twelve, came to our office on February 16, complaining of pain in the left ear. He had had more or less pain for the past ten days, but for the previous three nights it had been of sufficient severity to prevent sleep. He gave no history of an aural discharge at any time. Previous to the onset of this pain the patient never complained of trouble referable to his ears, but the mother stated that when a child, he had had a running ear during an attack of measles. Examination at this time disclosed a tender mastoid, more so at the tip with a moderate amount of edema typically located. The canal was dry; the drum bulged moderately at the poster-inferior quadrant; there was absence of a perforation, but there was quite marked sagging of the posterior-superior canal wall. The only notable feature that was not in harmony with the existing condition was the youngster's physical appearance. He apparently showed evidences of suffering from some sort of severe septic infection. He was pale and anemic, haggard looking, with an expression that was drawn and sickly. The rectal temperature was 103° F., pulse 104, respiration 26. His tongue was heavily coated; breath extremely foul. Immediate operation was advised, the child was admitted to the Bikur Cholim Hospital, and operated on the same day.

The interesting features of the operation are given as follows: The mastoid was completely uncovered and the cortex removed. The bone was unusually hard and sclerotic, the cells few and containing very little pus. The bony covering of the sinus was distinctly diseased, discolored, softened and necrotic and after being removed we found the sinus wall greenish in color, ulcerated and more or less collapsed. From the evidence at hand we decided that the sinus would require opening and probing and consequently we thought the safest and most rational procedure would be to limit dissemination of our infectious material and to accomplish this end we proceeded to the ligation of the internal jugular. The usual incision was made extending from the tip of the mastoid to the clavicle below. The vein was exposed but found to be normal throughout its whole extent and therefore was ligated but not excised. The incision was closed and a small drain inserted. We now again directed our attention to the sinus. The sinus wall was incised and about one drachm of pus evacuated. There was absolutely no bleeding from the sinus and we introduced a ring curette into the jugular end, and removed a number of large well organized clots as far down as and including the jugular bulb, but no free bleeding could be obtained. We then removed a number of blood clots along with pieces of thrombus from the torcular end, and here free bleeding soon occurred. A large portion of the diseased sinus wall was excised and the wound packed with iodoform gauze and covered with an outer dressing of saline.

The boy began to improve immediately after the operation. The temperature slowly dropped and in two weeks reached normal and remained so thereafter. The patient left the hospital three weeks after the operation well on the way to recovery.

This case presents four special features to which we wish to call particudar attention:

1. The infection through the sclerotic mastoid to the sinus took place with unusually great rapidity. The ear symptoms from the date of onset to the operation were only of ten days' duration.
2. The more pronounced symptoms indicating such a severe involvement were entirely lacking. Nothing that could be detected at the time of examination pointed to the possibility of such a serious complication. It should be remembered that this was an ambulatory case of sinus thrombosis.
3. The actual demonstration of pus in the sinus.
4. The absence of bleeding from the jugular bulb after removing all clots from the sigmoid below the knee to the bulb, showed conclusively that our thrombosis must also have extended at least into the inferior petrosal sinus. Nevertheless, nothing developed as a consequence.

IS TUBERCULOSIS CONTAGIOUS?

By G. K. DICKINSON, M.D., F.A.C.S.,

Jersey City, N. J.

THIS is an old question. Going back in our journals where we read of scrofula and phthisis we find it being asked and answered. Ignorance in pathogeny made it all excusable, but in these days with the increase in knowledge acquired there is little excuse. We are reminded of a sermon by Rev. Mr. Kelman, heard at St. George's in Edinburgh, in which he spoke of words being the clothing of thought, and that where we had accuracy in language we inevitably found accuracy of thought, and where we had lax thought there would always be laxity in language. It is inaccuracy in words, it is our careless way of expressing ourselves, which have led to inaccurate thinking, and we are getting

nowhere because we do not express ourselves in precise language.

Ghon, as well as Hamburger, have shown in numerous autopsies carefully made that the human tuberculosis germ enters the system through the lung. They both claim to have discovered the points of entry, from which the germs pass into the mediastinal glands. As the spirochete will make a little sore and pass into the system to hide, and, in many instances, not to demonstrate itself until late in life, so the tuberculosis germ leaves its litttle scar and passes to the glands at the hilum. These people are infected.

In the larger cities careful tests, von Pirquet, x-ray and physical examinations, show that 90 per cent of children under fourteen years of age are infected. In the rural communities it may be as low as 25 per cent. It is believed, and perhaps the belief is warranted, that these infected people cannot receive a secondary infection. The logical conclusion must be that tuberculosis is primarily a disease of the lymphatic glands, that it is a disease of childhood, that once a person becomes infected he will remain so as long as he lives, to give tangible expression of such infection by the invasion of the lung if conditions occur which will bring the bacilli out of the lymphatics into the blood stream.

Laennec was one of the first to announce that he had come to the conclusion that consumption, that is, tuberculosis of the lung, is not a contagious disease from man to man, that the danger of contagion is largely with children. Wilson Fox's experience of over twenty-seven years found but two instances of married couples infecting each other. Weber, in a much longer and larger experience, saw but nine cases, while West, who was on the lookout for such cases, found but one in the course of 25 years, and that could hardly bear investigation.

More recently Osler and others speak of the rare instances of apparent contagion between man and wife and between the invalid and the attending nurse. So rare is it, and so common is the disease in the system as acquired in childhood, that even these cases are probably open to suspicion.

In the late war numerous troops were sent to the front from the Far West in America, who had never been exposed, who were von Pirquet negative, and who on physical examination gave no evidence of invasion or infection. On reaching France they were quartered with other troops who became active in the lung—bacillary cases. There being an interval between the time they demonstrated symptoms and their segregation, these Western troops were exposed. It is an interesting conjecture whether they will become infected and demonstrate it later in life. To date there has been no such evidence.

Now the answer to the question: "Is consumption or tuberculosis contagious?" will depend upon the accurate understanding of the question and its meaning. It is positively contagious to each and every child, as subtle as measles, but generally producing an infection. The patient with tuberculosis of the lung, spitting active bacilli, has not as yet been demonstrated a danger to the adult by any clinician who thinks logically and expresses himself accurately.

In our experience in the Tuberculosis Clinics of Jersey City no von Pirquet negative or *x*-ray negative case in the adult, whether nurse, attendant, or physician working in our tuberculosis institutions, has ever come down with an active process in the lung. All of our attendants are given careful examinations before employment. A number of them show infection; many of them show healed lesions; a large percentage are in a position to explode on provocation. These are the ones which the general profession say "caught it."

280 MONTGOMERY STREET.

Medicolegal Notes.

Suit for Penalty for Practising Without License Is Civil in New Jersey.—A suit by the New Jersey State Board of Medical Examiners for a penalty for the practise of medicine without a license in violation of the New Jersey Medical Examiners Act, 3 Comp. St. 1910, p. 3329, as amended in 1915, is held to be a civil suit and it is proper to award venire and to try the case before a jury. The language of different sections of the act is incongruous, and provisions may be cited which afford an argument for either side. Upon the whole the trend of the prior decisions has been to hold that the proceedings are a civil suit. It was urged that the trial judge should have directed a verdict for the board. The evidence was suggestive that the defendant in one case at least undertook to diagnose and prescribe, but his testimony was that he merely sold medicine and avoided any attempt to make a diagnosis or prescribe. He came very close to admitting facts sufficient to sustain the charge, but whether he did admit it was held to depend on what he in fact said and what he in fact did. In view of the somewhat different versions it was held a jury question was presented. Judgment for the defendant was affirmed.—State Board of Medical Examiners v. Curtis, New Jersey Supreme Court, 110 Atl. 816.

Hospital Treatment Under Statute Provisions.—Missouri Rev. St. 1909, § 1465, as amended by Laws 1919, p. 200, provides that patients having no ability to pay shall be received for treatment in the Mt. Vernon Sanatorium, and that if a person desiring free treatment shall apply under oath to the county court, or if a resident of the city of St. Louis to the comptroller, the latter shall at once certify the name. A writ of mandamus was sought to compel the comptroller of the city to certify the name of a resident to the superintendent of the Sanatorium for the treatment of incipient tuberculosis.

It was held that the comptroller, on proper application being filed, is bound to certify the name of the applicant without investigating the applicant's ability, notwithstanding that the comptroller is charged with the responsibility of conserving the financial interests of the city, which in the end must pay for the treatment; the words "at once" meaning with reasonable haste in the circumstances, and not entitling the comptroller to a reasonable time to investigate the truth of the affidavit. The policy or impolicy of the statute in including the city was held to be a matter for the legislature and not for the courts, the statute being valid and unambiguous.—State v. Nolte, Missouri Supreme Court, 218 S. W. 862.

Different Theories of Injury Due to Trauma Not Inconsistent.—In an action for personal injuries, in which one of the plaintiff's expert witnesses diagnosed her trouble as "traumatic neuritis," and another, who examined her some two years later, found her suffering from "traumatic neurasthenia," both nervous troubles originating from external violence, attributed by each to the shock, blow, or fall she received at the time of the accident, and each in effect expressed the opinion that she might also be suffering to a degree from the related nerve disease or disorder which the other expert designated, it was held that if the jury believed the plaintiff's testimony and that of her witnesses, the difference in the testimony did not render the damages awarded double or excessive.—Oliver v. Detroit Taxicab Co., Michigan Supreme Court, 177 N. W. 235.

THE DIAGNOSIS OF HEPATIC INSUFFICIENCY BY MEANS OF ALIMENTARY GLYCOSURIA.

IT IS unquestionable that alimentary glycosuria is an important semiological element for the appreciation of the functions of the hepatic cell, although there are lesions of the liver which will not give rise to the glycosuria in spite of a morbid change in the hepatic cell. The individual resistance is an extremely important factor which depreciates the value of every clinical symptom. On the other hand, in certain cirrhoses where the portal circulation is greatly obstructed it may be supposed that the hepatic cell is still sufficient to carry on its glycogenic function and it is also a fact that an alimentary glycosuria sometimes occurs in apparently perfectly healthy subjects, but nothing proves that in them the hepatic cell is not to some extent pathologically involved.

Now, "arthritism" is a frequent cause of morbid changes in the hepatic cell because, consequent upon a general state of debility of the metabolism, the body manufactures a larger number of toxins, so that from birth the work imposed upon the liver will be more considerable. Therefore, at a given time the liver will become insufficient when called upon to deal with a very considerable amount of carbohydrates or toxic matter. This insufficiency is but temporary, but if the cause be durable it will in turn become permanent and the disease constituted. Hepatic diabetes is an example and is largely met with among gouty subjects. At the onset it is intermittent and inconstant, the glycosuria appearing only after meals; but if the subject is not quickly put upon a proper diet it will become permanent. All this applies to patients with gout, obesity, and gastric dilatation, who present an alimentary glycosuria when the test is made. Strictly speaking, these people are not ill; their liver functions are normal and sufficient, but may be compared with congenitally small arteries. Quite capable of transforming a certain amount of sugar into glycogen, the organ becomes insufficient for this transformation when larger quantities are brought to it; it is suddenly overwhelmed with work, becomes insufficient, and allows the sugar to pass into the urine.

Alimentary glycosuria is the index of this latent intermittent "hepatic claudication" as it has been aptly called by French writers, or a visceral meiopragia, as Petain was wont to say. On the other hand, hepatic insufficiency can be produced by infections or intoxications which suddenly or progressively change the hepatic cell or diminish its resistance. Therefore, it can be understood why alimentary glycosuria is met with in catarrhal icterus. The latter process is not due, as was formerly thought, exclusively to occlusion of the excretory bile ducts; it is almost always the outcome of a true hepatitis, a morbid change in the liver cells due to infectious or toxic products derived from the intestine and carried to the liver by the portal vein or bile duct. Whenever the hepatic cell is pathologically changed, its glycogenetic function will be disturbed so that the absorption of a certain amount of sugar will result in glycosuria. But several factors may give a positive result of the test; and first of all the condition of the nervous system, which possesses such great influence over the liver, must be considered. Medullary lesions, diffuse cerebral processes, and the neuroses sometimes give rise to alimentary glycosuria. Gastric lesions, dilatation or various types of gastritis, and intestinal affections almost invariably give rise to disturbances of gastrointestinal absorption. By causing a prolonged sojourn of sugar in the digestive tract, they favor its destruction by fermentation, while disturbances of renal elimination, by prolonging the sojourn of sugar in the blood, also favor its destruction by the tissues of the organism.

Now, it is easy clinically to place these two causes of error in evidence. A subcutaneous injection of methylene blue will reveal the disturbance of the renal permeability, while the state of absorption of the gastric mucosa can be estimated by the ingestion of five centigrams of the same hydrocarbon. These disturbances of absorption and elimination greatly influence the production of alimentary glycosuria. When absorption is defective the minimum of ingestion increases it if the liver is intact, but decreases when the liver is diseased. The same results are observed when renal permeability is diminished. Finally, if the disturbances of absorption are combined larger doses of sugar are required to produce glycosuria.

The coexistence of alimentary glycosuria with urobilinuria and hypoazoturia is one of the best evidences we have of hepatic insufficiency. Alimentary glycosuria should always be sought for in every case where this syndrome is suspected, but if sugar does not appear in the urine the renal permeability and the state of the gastrointestinal functions should be tested by the usual clinical procedures before integrity of the liver is admitted.

THE DIETETIC TREATMENT OF DIABETES.

WHEN one speaks of the treatment of diabetes one means, as a matter of fact, dietetic treatment. The treatment of the disease is essentially dietetic; as a rule, if the diet be arranged in accordance with the particular type of the disease from which the

patient is suffering, no other form of treatment is necessary. According to Dr. P. J. Cammidge, who writes on the subject in the *Prescriber* for October, 1920, the first step to take is to discover the type of case. He provisionally classifies diabetics into three main groups: 1. The purely pancreatic; 2, The purely hepatic; 3, A residuum many of which are probably nervous in origin. The differential diagnosis of these types depends partly upon the results of exhaustive analyses of the urine, feces and blood, partly upon the chemical data, and partly upon the effects of treatment. As a rule the hepatic form occurs in elderly people, although it is seen in children. The pancreatic patient is generally young, between 15 and 40; is usually under weight, and is losing flesh rapidly; a history of gastrointestinal catarrh or some infection, such as influenza, preceding the onset of glycosuria is not uncommon. The nervous type of diabetes may occur at any age, but is most common between twenty and thirty; the patient is generally high strung and neurotic, and often gives the history of some mental shock or business worry.

Cammidge insists that whatever the type of case, and no matter what treatment has been found most suitable in the first instance, the after treatment must be arranged with three objects in view: first, the provision of, at least, a maintenance diet; second, the prevention of the further progress of the disease; and, third, such an arrangement of the diet as will ensure variety and a physiological balance of its constituents. It is pointed out that, although loss of weight is generally regarded as a very serious symptom in diabetes which must be prevented at any cost, it is really an attempt on the part of Nature to cure the disease, and within reasonable limits should be encouraged. If he is over the weight which his defective powers of metabolism can maintain without strain, these powers are likely to diminish through overwork, but when the work is well within their capacity, sufficient physiological rest can be obtained to allow of recuperation and a consequent improvement in function. In most instances, where the liver is the organ chiefly at fault, a moderate loss of weight is sufficient to balance the functional capacity of the organ and the mass of the tissues, so that a maintenance diet is secured without difficulty. With mild pancreatic cases the same holds good, but where there is advanced pancreatic insufficiency it is often difficult, and even impossible, to arrange a diet which will secure adequate nutrition and yet prevent further progress of the disease. The first two conditions are fulfilled by discovering for each patient his total dietary tolerance, and at the same time so reducing his weight that the work his defective organs are called upon to perform will be well within their limits. The third condition is the most commonly neglected and is the most fruitful source of relapse and complications. Cammidge explains how a diet can be arranged which will ensure variety and a physiological balance of its constituents, but the explanation is too long to deal with in the way its importance deserves. The salient points of this most excellent article are that treatment of diabetes is essentially dietetic, but that such treatment is of little avail unless the types of diabetes are correctly differentiated and each type treated in accordance with its particular characteristics. It is here that the ordinary practitioner so often fails in his treatment of diabetes. He does not differentiate between the different types frequently, because for various obviously valid reasons he is unable to do so, and treats the disease accordingly. He may follow closely the dietetic principles of treating the malady, but if he does not diagnose quite accurately his treatment will be a failure or will not be so successful as it should be. Special scientific dietetic treatment is indicated for diabetes. This treatment, however, cannot be given properly unless one knows exactly when it should be given; it is advisable, therefore, that in cases of diabetes a specialist be consulted. It is one of the diseases in which special knowledge is required in order to deal with it with any great hope of success.

IS LUDWIG'S ANGINA A GAS PHLEGMON?

Is the malady known as Ludwig's angina an ordinary phlegmon in the affected area, or a disease *sui generis?* If the latter, is it essentially a form of gangrene? Peyre, a practitioner of Algiers, attempts to answer this question in *La Presse Médicale* for November 3, 1920, xxviii, 80. A case is described which followed extraction of a tooth. The diagnosis was made on sight, although the affection was in its inception. The floor of the mouth was swollen and the patient complained of malaise and chills. Trismus made examination very difficult. The suprahyoid region was the seat of a hard edema —a so-called woody phlegmon. Having the experience of two previous cases in his mind, the author at once made a mentohyoid incision without waiting for an anesthetic. From this wound escaped a fetid brownish liquid and some gas. Counter openings were also made and the finger was used to evacuate the sphacelated connective tissues. Dakin's fluid was used to irrigate, and the patient seemed to be doing well when chills reappeared. The original wound was in good shape but the left cheek was swelling, the edema involving the orbit and eyelids. The ophthalmic veins and cavernous sinus were menaced. The cheek was incised from the commissure to the ascending ramus and the process repeated. The state of the patient continued to give alarm for ten days when a third focus appeared over the temporal bone to the left and was treated in the same manner, this time without further developments.

This case of gas gangrene is called by the author a typical one of angina Ludovici. Most textbooks state that the disease may end in resolution, abscess, or gangrene, the latter being clearly regarded as an occasional sequel and not the essence of the disease. While the disease was once regarded as streptococcus infection, of late various anaerobes have been accused, including the perfringens. The gangrenous

theory is not new and long ago Ludwig's angina was held by some to be an example of primitive gangrene and not of phlegmon.

According to Peyre much the same question was debated in 1892. So far as the gangrenous process was concerned it was an especially deadly disease, the mortality alone serving to distinguish it from other suppurations in the cervical region which usually originated in the lymphnodes. The lethal factor was a "sepsis" save where the process caused suffocation. Demoulin, who once reported eight cases, states that in seven there were marked gas symptoms. If a phlegmonous process ends in gangrene we may of course speak of a gas phlegmon and it was shown during the war that gas gangrene and gas phlegmon are indistinguishable from each other. Although his views are not endorsed by all surgeons, the author believes we are safe in regarding Ludwig's angina as an example of gas gangrene or gas phlegmon.

INFANTILE SPASTIC HEMIPLEGIA OF HEREDOSYPHILITIC ORIGIN.

INFANTILE spastic hemiplegia and hereditary syphilis upon more than one occasion have been found to exist simultaneously in the same subject. This coincidence is uncommon, but nevertheless it is more than probable that it is not one of chance and that there exists a relationship of cause and effect between the two processes. The reasons for this conclusion are, firstly, that at present it is an unquestioned fact that infectious processes are very often the cause of infantile spastic hemiplegia and there is no valid reason why syphilis—a preeminently infectious disease—should not produce this nervous affection; secondly, syphilis is capable of creating cerebral lesions similar to those produced in infantile spastic hemiplegia. Besides the gumma and sclerosis, syphilis engenders vascular changes susceptible of ending—under certain influences—in cerebral hemorrhage or softening. The lesions of infantile spastic hemiplegia are for the most part of vascular origin and are often the sequelæ of old hemorrhagic foci or softening.

It is as yet impossible to determine under what conditions or influences a child with hereditary syphilis will develop the syndrome of infantile hemiplegia. However, traumatism on the head, nervous heredity, febrile diseases, and still other factors may favor the localization of the spirochete in the brain. The lesions created by syphilis and capable of giving rise to infantile spastic hemiplegia are of three orders, namely, (1) lesions of luetic nature, that is to say, specifically syphilitic; (2) lesions in themselves nonspecific but secondary to syphilis, and (3) parasyphilitic lesions.

The diagnosis of this affection is easy, but the syphilitic basis is sometimes difficult to recognize. In all the cases the stigmata of hereditary syphilis must be carefully looked for on the child himself, as well as his brothers and sisters. The Wassermann reaction is not to be relied on in these hereditary cases. If this search is always made thoroughly, hereditary syphilis will more often be accused as the factor of spastic hemiplegia. The differential diagnosis must be made from syphilitic pseudoparalysis and all those morbid processes which may accompany hemiplegia — tuberculous meningitis, cerebral tumors, choreic and hysterical hemiplegia, and with those affections which may simulate the spastic type—infantile spinal paralysis, spastic tabes dorsalis, obstetrical paralyses, and sclerosis *en plaques*. The diagnosis of the primary lesion which has given rise to the spastic paralysis will be found practically impossible in all cases.

The prognosis as to life is serious only during the first phase of the process. The gravity of the affection depends upon the infirmities which ensue and the developmental arrests, both intellectual and physical, which are its ordinary consequences. Occasionally other visceral complications of syphilis are to be feared. The newer specific treatment is to be essayed in all cases, and should be energetically employed from the start, but when the affection is of some standing it will remain without effect.

THE CHRONIC FORMS OF PUERPERAL METRITIS.

THE chronic forms of puerperal metritis are more common than the acute types, whether they directly follow the latter or appear at a later date at a time when the uterus offers more resistance. The chief characters of the chronic forms are a dextroversion of the uterus, the organ presenting a very peculiar cylindroid shape with intense sensitiveness to pressure. The cervix is gaping and its walls are thickened. There is a tendency to a lowering of the vagina and uterus, while the leucorrhea is less intense than in gonorrheal metritis and the large mucous plug characteristic of the latter process is wanting in the puerperal form. A relatively common variety of puerperal metritis, especially following miscarriage, is due to retention of a bit of placenta, and has been improperly called hemorrhagic metritis, because it may be aseptic, at least at its onset. The expulsion of clots, an increase in the size of the uterus, and a gaping cervix are the ordinary symptoms. Of no lesser interest are the parenchymatous forms of metritis which result from a leucocytic infiltration which in turn sets up a process of diffuse sclerosis with a tendency to involve the entire uterine body, hence a considerable increase in the size of the organ and an excessive vascularization. This type of chronic metritis almost invariably causes a sharp reaction in the bladder and rectum and gives rise to other troubles such as dyspepsia, palpitations, and nervous disturbances. Severe abdominal pain, increasing at the time of the menses, is prone to occur, and if the patient is examined at this time a kind of edematous infiltration around the uterus will be detected. The enlarged uteri, with gaping cervices, become infected upon the slightest occasion, hence the frequency of relapses of the process. Finally, the ovaries may undergo pathological changes, sclerous or sclerocystic degeneration being probably the most common. The development of a metritis in a recently delivered female may be due to gonorrhea. This is a mixed metritis in which the infec-

tion results from a preexisting gonorrhea that has remained localized in the cervix up to the time of labor and then rapidly invades the uterine cavity during the puerperium. It naturally gives rise to a discharge whose peculiar character resides in the causation of considerable irritation of the labia majora and especially the internal aspect of the thighs resulting in eczematous dermatitis with lichenoid formations. The treatment of the hemorrhagic types of puerperal metritis is by curettage, but in the late and mildly virulent forms of the process swabbing the uterine cavity with tincture of iodine and formol will be found satisfactory. Finally, parenchymatous metritis with delayed involution should be dealt with by rest in bed, kinesitherapy, and balneotherapy.

Side Lights on the Marquis of Sade.

Under the title "The Admirable Marquis of Charenton," a writer in *Le Progrès Médical* for August 21, 1920, xlviii, 34, gives an account of some little-heard-of experiences of a character known almost solely for a vice to which his name has been applied and with which we are not here concerned. At Charenton was a famous lunatic asylum in which the marquis was interned in 1803 for the second time at the request of his family and the police. It was an asylum *de luxe* for the wealthy and in charge of the clergy, who sought to divert their charges with theatrical displays and which contained a theater. On his admission, Sade was placed in charge of the theatrical activities. He selected the plays and made up the casts as far as possible from the inmates, with professionals and others to eke out. Some well-known women assisted, and the hospital surgeon was conscripted, but the physician in chief, Royer-Collard, who was for some reason *persona non grata*, was not allowed to take part. The actual head of the hospital and religious activities was the Abbé Coulmier, and when Cardinal Maury, Archbishop of Paris, visited Charenton, the choir sang a cantata *"Des mon enfance"* of which the author was Sade. After some time the latter wished for his freedom, but this was not granted, and subsequent efforts also met with failure. Royer-Collard now petitioned to have the theater discontinued and the prisoner deprived of his excessive liberty; for the Marquis had changed his demeanor when his plea was denied and became a good deal of a nuisance. There were two parties, one of which wished to be rid of him while the other upheld him. It was finally decided to hold him at Charenton and he became a model inmate once more, dying in 1814. He was interred there and eventually the madhouse was changed to a maternity hospital.

Serum Treatment of Epidemic Poliomyelitis.

The great hope of remedial and curative treatment in certain forms of disease hinges to some extent on the success of vaccine and serum therapy. It is difficult to say with any degree of exactitude whether modern vaccine or serum therapy has achieved great results. Opinions are divided on the subject. With regard to the serum treatment of epidemic poliomyelitis, Dr. Hugh Thursfield, reviewing recent work on children's diseases (*Practitioner*, October 1920) quotes from an article by Dr. Rowan which appeared in the Medical Record, December 13, 1919. He points out that the infective agent of poliomyelitis is generally believed to be a filtrable virus, and that the efforts of Flexner and his associates to produce an efficient serum have not, on the whole, been successful, though a certain degree of success has been attained. He then refers to the isolation by Dr. Rosenow of the Mayo Foundation of a streptococcus, which he believes to be intimately connected with the causation of the disease, and who has produced a serum with which it is claimed that remarkable results have been secured. Among those who have recorded great success with this serum was Dr. Rowan of Dubuque, Iowa, who gave an account of the results in an epidemic of poliomyelitis which occurred in that town in the Summer of 1918. Thursfield states that the article in question afforded very little information concerning the serum, and therefore judgment must be delayed on the point. It would be instructive and extremely valuable information if Rosenow would give further details of the serum and an account of the results generally brought about by its use.

News of the Week.

Increase in Child Labor.—The National Child Labor Committee, in announcing Child Labor Day, to be observed in churches, synagogues, schools, colleges, and clubs throughout the country in January, 1921, gives out some interesting figures showing an increase in child labor. Fourteen States, it is announced, show an increase in child labor during the first six or eight months of 1920. In New York City 5,283 more children applied for work permits during the first half of the year than in the corresponding period last year. The last three months, however, show a decrease in applications, bringing the total increase to date down to 2,353. Baltimore county, Maryland, shows an increase of 4,064 in application for work permits up to October 31, 1920, than in the corresponding months of 1919. Chicago authorities report an increase, during the summer, of 13,000 in that city. In Minnesota there has been an increase of 193 per cent since 1915.

New Surgeon-General of the Navy.—President Wilson approved the application for the retirement, effective November 26, of Admiral W. C. Braisted as Surgeon General of the United States Navy, and appointed to the position Admiral Edward Rhodes Stitt, of the Naval Medical School, a distinguished authority on tropical diseases. Admiral Stitt was graduated from the Medical Department of the University of Pennsylvania in 1889, and entered the Naval Medical Service the same year as Assistant Surgeon. He was made Rear Admiral in 1917. During the World War, he performed valuable service in connection with the preparation at the Naval Medical School of the medical officers newly inducted into service with the Navy.

Smallpox in Haiti.—According to cable advices from Rear Admiral Knapp to Secretary Daniels, more than three hundred cases of smallpox had developed in Haiti up to November 22. Smallpox serum from the naval hospital at Washington was immediately rushed to Haiti. The disease is of a

mild type, it was reported, only one death having occurred.

"Seal Your Mail With the Stamp of Health."—This is the slogan of the Christmas Seal Campaign of the Committee on Tuberculosis and Public Health of the State Charities Aid Association. Doubtless the 700,000 homes in the State, to which letters have been sent, as well as many thousands not so approached, will respond to this worthy appeal.

Drive for Mental Convalescents.—With the objective of $50,000, a two weeks' campaign has been undertaken to augment the building fund of the Home and Farm Institution for Mental Convalescents. It is proposed to erect an institution on Long Island, where the mentally afflicted may be restored to health and vigor through proper environment and treatment. Dr. Menas S. Gregory, of the Psychopathic Department of Bellevue Hospital, is medical advisory chairman of the organization.

Malnutrition in New York City Schools.—The annual report of the Children's Aid Society, recently issued, gives interesting figures concerning the prevalence of malnutrition among school children. Investigation by the Society in ten schools revealed that from 20 to 67 per cent. of the children were suffering from malnutrition, while from 12 to 35 per cent. were classified as needing immediate medical attention for ailments that prevented proper physical and mental development. The general average of malnutrition among public school children of the city is given as 20 per cent., and that of children needing medical attention as 4 per cent.

Automobile Fatality Rates.—Frederick S. Crum, in the *Spectator*, gives a table of comparative automobile fatality rates in thirty-eight American cities. The thirty-eight cities combined showed rates of automobile fatalities, per 1,000,000 population, of 77.9 in 1915, and 142.3 in 1919, an increase of 82.7 per cent. New York City occupies the seventeenth place in the list, with a rate of 66.1 in 1915 and 137.5 in 1919, a percentage of increase of 108.0. Basing his figures on the registration area covered by the Census Office, Mr. Crum states that nearly 10,000 persons were killed by automobiles in the United States, exclusive of Alaska, during the year 1918.

Positions for the Blind in Boston Stores.—The Massachusetts State Commission for the Blind has under consideration a plan whereby, if it materializes, certain stores in Boston will give positions to blind men and women. Some of the merchants are said to have offered to furnish departments in their stores to be conducted entirely by those who, as the result of war injuries or other causes, have lost their sight.

Asthma and Hay Fever Clinic.—The first public clinic in New York City for the serum treatment of asthma and hay fever has been established at the New York hospital. The clinic is in charge of Dr. Robert A. Cooke.

Associate in Clinical Psychiatry and Psychotherapy Wanted.—The United States Civil Service Commission announces an open competitive examination for associate in clinical psychiatry and psychotherapy. A vacancy at St. Elizabeth's Hospital, Washington, D. C., at a salary of $2,500 a year and maintenance, and vacancies in positions requiring similar qualifications, or this or higher or lower salaries, will be filled from this examination. Applicants should apply at once for Form 2118, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the Secretary of a local Civil Service Board. Applications close December 28.

Medical Interne Wanted.—The New York State Civil Service Commission announces an open competitive examination for medical interne for St. Elizabeth's Hospital, Washington, D. C., at a salary of $1,200 a year and maintenance. Other vacancies at this or higher or lower salaries may be filled from this examination. Applicants will be rated as received until March 1, 1921. Applicants should apply for Form 1312, stating title of examination desired, to the Civil Service Commission, Washington, D. C., or to the Secretary of a local Civil Service Board.

Harvey Society Lecture.—Dr. Carl J. Wiggers of the Western Reserve University, will deliver the fourth Harvey Society Lecture at the New York Academy of Medicine Saturday evening, December 11. His subject will be "The Present Status of Cardiodynamic Studies on Normal and Pathological Hearts."

Charitable Bequests and Gifts.—By the will of Jacob Wertheim, of New York City, who died November 14, the sum of $100,000 is left to the Federation for the Support of Jewish Philanthropic Societies. Announcement was made November 24 of a gift by John D. Rockefeller, in memory of his late wife, of $63,763,357.37, for the benefit of public institutions and charities, of which women and children are the chief beneficiaries. This brings the total sum of Rockefeller donations up to $475,000,000.

Sir Berkeley Moynihan of Leeds, England, was elected to Honorary Fellowship in the New York Academy of Medicine, at the stated meeting of that body on November 18.

Dinner to Dr. E. L'H. McGinnis.—The Womans' Hospital Society gave a dinner to Dr. E. L'H. McGinnis on November 16 at the University Club. There were some forty members and guests present. The dinner was given in recognition of the work done by Dr. McGinnis during his many years of service at the Woman's Hospital.

Dr. Sarah J. McNutt has removed her office from 265 Lexington Avenue to the Park Avenue Hotel, between 32d and 33d Streets.

Dr. Otto V. Huffman has removed his office to 25 East Sixty-fourth Street, New York City.

Research Information Bureau.—The National Research Council has established a Research Information Service as a general clearing-house and informational bureau for scientific and industrial research. This "Service" on request supplies information concerning research problems, progress, laboratories, equipment, methods, publications, personnel, funds, etc. Requests for information should be addressed, Research Information Service, National Research Council, 1701 Massachusetts Avenue, Washington, D. C.

Neuropsychiatric Patients in Marine Hospital.—The United States Public Health Service will soon convene in Pittsburgh a board consisting of Dr. A. J. Ostenheimer, of Philadelphia, Dr. T. Diller, of Pittsburgh, and the officer in charge of the Marine Hospital to arrange for the setting aside in the

hospital of a section for the diagnosis of neuropsychiatric patients from the third district of the Service, comprising the States of Pennsylvania and Delaware.

Segregation Urged in Drug Habit Cure.—John S. Kennedy, President of the New York State Commission of Prisons, in a recent report on the municipal farm for drug addicts on Ricker's Island, urged the segregation of criminal from non-criminal addicts. When Commissioner Kennedy visited the farm recently it had 275 inmates, 65 of whom were self-committed and 49 of this number had never been in an institution before. One man told the Commissioner that he had come to New York from Tennessee for treatment. Although he was well supplied with money to pay for his care he was sent to the municipal farm to be treated at city expense. It was found, according to the report, that while the self-committed addicts had a separate dormitory and separate tables at mess, they are in almost all respects on the same basis as those convicted of crimes and serving sentences. They wear the departmental criminal uniform, work the same and are under the same discipline and subject to punishments as the delinquent inmates.

Doctor Again Seeks Whiskey Blanks.—Dr. Melville A. Hays of New York City states that when a book containing one hundred blanks to prescribe whiskey to patients for medicinal purposes had been used he was refused a new one. Through his attorney he asked the Federal Court for a mandatory injunction requiring the Prohibition Director to furnish him with a book of blanks.

Medical Society Elections.—THE NEW YORK ACADEMY OF MEDICINE, at its stated meeting November 18, 1920, elected the following officers: *President*, two years, Dr. George David Stewart (re-elected); *Vice-President*, for three years, Dr. E. L. Keyes, Jr.; *Corresponding Secretary*, three years, Dr. D. Bryson Delavan; *Treasurer*, three years, Dr. Seth M. Milliken; *Trustee*, five years, Dr. Nathan E. Brill; *Member of Library Committee*, five years, Dr. J. J. Walsh; *Member of Committee on Admission*, five years, Dr. Nellis B. Foster.

THE MEDICAL SOCIETY OF VIRGINIA, at its fifty-first annual meeting, held at Petersburg, October 27 and 28, elected the following officers for the ensuing year: *President*, Dr. A. L. Gray of Richmond; *First Vice-President*, Dr. E. C. S. Taliaferro of Norfolk; *Second Vice-President*, Dr. F. J. Wright of Petersburg; *Third Vice-President*, Dr. Hunter H. McGuire of Winchester.

"Police Day" for Police Hospital.—A day is to be set aside by theaters as "Police Day," part of the proceeds to be contributed to the Police Hospital. At a luncheon recently given by Commissioner of Police Enright to theatrical and motion picture men was marked by the contribution of $75,000 for the hospital, which is to be erected near the entrance to Prospect Park, Brooklyn.

Obituary Notes.—DR. WILLIAM ADAMS DAYTON of New York City died November 19, at the age of sixty-two. He was graduated from the College of Physicians and Surgeons in 1880.

DR. JAMES B. GERE died suddenly at his home in New York City November 18, at the age of forty-eight. He was graduated from Bellevue Hospital Medical College in 1896. Dr. Gere served as major in the Medical Corps with the Seventh Regiment during the World War. He was a member of various state and local medical societies.

DR. MARK I. KNAPP of New York City died November 26, at the age of fifty-two. He was graduated from New York University Medical College in 1894, specializing in gastroenterology. He was a member of the American Medical Association.

DR. F. E. W. HOPKE of Brooklyn, N. Y., died November 23 from injuries received when he was run down by a motor. He was graduated from New York Homeopathic Medical College and Flower Hospital in 1899, specializing in pediatrics.

Correspondence.

VACCINES FOR WHOOPING COUGH.

TO THE EDITOR OF MEDICAL RECORD:

SIR:—Having just read the article by Dr. Freeman in your issue of Nov. 6, 1920, I wish to contribute my mite to the subject as a general practitioner in a country town. During the past summer and fall I have used pertussis combined vaccine in eighty-two cases for the prevention and treatment of whooping cough. The vaccine was obtained in Columbus in 5 c.c. vials and was said to be "fresh." Just what this word meant as to time I do not know.

The epidemic was very severe and there were numerous deaths from pneumonia and malnutrition combined with pertussis. All my cases were treated alike as to dosage and no other treatment was given. Two minims was the first dose, four the second, and eight the third. Additional doses were of ten minims. Three doses were the minimum number and six the maximum. Babies three days of age were given the same size dose as the older children.

The cases came voluntarily and no promises of prevention or cure were held out to the parents. Some of the patients had not been exposed; some had been exposed but had not yet shown symptoms of the disease; some were in the beginning and some well advanced in the malady. A few were very ill. Two had catarrhal pneumonia when the first dose was given. Many had vomiting of meals and greatly disturbed nights. Several had lost appetite and were losing weight rapidly. In fact the epidemic was severe and parents with babies were much concerned for their safety.

In order that this letter may not be too long I shall condense the data as much as possible. Four babies under one week of age were vaccinated because some member of the family had pertussis at the time of their birth. One of these contracted the disease after three injections and three more of maximum size were given at two-day intervals. A good and prompt recovery followed, although the baby gained nothing in weight for several weeks. The others did not contract the disease. One baby three months old with marasmus and enterocolitis, artificially fed, was vaccinated in the third week of the disease and died before the second dose was given. The babies with pneumonia and bronchitis made good and rather rapid recoveries. Of the whole number the majority were so far along in the disease when the first dose was given that the parents were certain of the diagnosis. In several families of four to six children there would be one

or more not apparently benefited to the extent of the others. About eighty-five per centum of the whole number of eighty-two were benefited so apparently and promptly that the result was surprising alike to the parents and myself.

In five families where the older children contracted the disease first and the younger ones were just taking it when the disease was at its height in the older ones, I vaccinated only the younger ones, and the difference in the severity and length of the disease was very apparent.

Upon the whole I am enthusiastic about the results, as all except the ones noted made rapid and good recoveries without complications other than those existing at the time of the first dose. As a preventive the result was equally gratifying. Parents were even more sanguine than myself in their belief in the curative power of the vaccine.

I know full well that one swallow does not make a summer, and I appreciate at its full value the danger of drawing conclusions from so few cases and these in a general practice. I began the vaccines a doubter in their efficiency. I kept a record of the age of each patient, the stage of the disease, the severity of symptoms and the complications if any, and I had the parents report after the treatment was over when they considered the patients well. Also parents were asked to give me their opinion of the results obtained. From these data, I must say the treatment was successful far beyond my expectations in about eighty-five per cent. of the cases. There were no unpleasant symptoms from more than two hundred and seventy-five injections, all in the arms. There were no sores beyond the local redness, which was the greatest after the largest doses. There was no fever which the parents observed and nothing but good could be attributed to any of the vaccinations. Babies often slept through the process of vaccination. Older children seldom cried, only the very sensitive and nervous made objections and in these cases the few tears were soon dried.

HOWARD JONES, M.D.
CIRCLEVILLE, OHIO.

THE ELIMINATION OF FEAR.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—As a fellow practitioner studying American ideals and seeking progressive innovations, may I, in the spirit of helpful criticism, offer our coworkers a few suggestions which may aid in eliminating fear in surgery and medicine.

Though we appreciate the advantages accrued to both patient and doctor in securing the faith and tranquillity of mind of the patient, do we seriously endeavor to eliminate his fear and study the real causes and remedial methods for overcoming the faint-heartedness we wrongfully attribute to one seeking medical aid? How often do we regard augmented pulsation, tremor, sudden pallor, and other visible indications of distress on the part of the patient presenting himself for examination, consultation or operation, as due to nervousness, suppressed excitement, adrenal flow and natural fright?

I find that equanimity can be maintained and restored by a soothing objectivity, *id est*, those things and influences outside the person which, through an appeal to the senses, are comforting, health-bringing, and hope-restoring. Make the environment overcome the patient's misgivings and inculcate complete confidence. Consider the soothing effects of a small, well-furnished room, with shaded lights, harmonious color combinations, and with instruments, bottles, and apparati carefully concealed. Consider the perturbing influences of glary lights. Consider the glare produced by white through its reflection of all the colors of the spectrum and its resulting startling effect. Make the surroundings cheery and homelike, and all which the patient is accustomed to in an atmosphere of refinement, rather than label the place "physician's office," "dentist's office," etc. Make your patient comfortable. Eliminate the "doctory" aspect. Make it homey. I believe that is half the secret of eliminating fear in surgery and medicine.

F. F. VAN COURT, M.D.
RITZ-CARLTON HOTEL,
NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Nov. 5, 1920.

International Health.—Professor F. F. Roget in his second Chadwick lecture—reference was made to the former lecture in a previous letter—dealt with tuberculosis. He pointed out that the preventive mode of giving to human beings an environment and a nutrition as free from germs as possible, should not be applied irrespectively of the segregation of tuberculous persons and keeping them apart from the healthy for any necessary length of time. In the third lecture, given on Oct. 29, Professor Roget discussed the work mapped out for the Public Health Department of the League of Red Cross Societies. The work is divided into seven sections dealing respectively with social diseases, venereal diseases more especially, the prevention of malaria, tuberculosis, preventive medicine, child welfare, nursing, and education. He drew attention to the fact that serious difficulties attended this inclusion of venereal diseases in Red Cross work, such diseases being more suitable for the ministrations of the medical officer and the private physician. As for the resolutions of the Medical Advisory Board of the League as affecting child welfare and nursing, the speaker said that the General Council of the League of Red Cross Societies met in Geneva, March, 1920, for a week, 27 societies being represented. The medical resolutions passed by this Council came before the Medical Advisory Board, which met for the first time in July of this year. Child welfare as defined by this board, included all measures to be adopted for children before and after birth, the hygiene of the mother and child, the supervision of growth, and protection from communicable diseases, especially tuberculosis. Analogous to the cry "Back to the land," the cry "Back to the child," implied the scattering far and wide of the child welfare scheme, which must be based on the sympathetic support of doctors and on the education of the public. It lay with the Red Cross societies to provide doctors to produce the largest possible number of modern nurses duly trained, and to create schools or centers for instruction. All this should tend to one end. The education of the public of great importance was the formation of

a child welfare unit, consisting of an instructed group of workers with proper equipment, which would be sent to places where child welfare work was most difficult. It was hoped that such a unit would form a nucleus from which a knowledge of the science of child welfare would spread in every country throughout the world. Professor Roget insisted that there was no way in which a woman could better serve the community than by nursing.

The work of the Red Cross in civil communities involved the utilization of women health workers in the organization of society. No work of social relief could be better suited for Red Cross organization in time of peace than child welfare work. The entire trend of the address was to impress upon his hearers that the welfare of children was almost wholly the concern of women, and he contended that each socially unemployed woman of any country should take upon herself the care of a child or children. He pointed out that the work was not charitable but humanitarian.

Maternity and Child Welfare.—As Professor Roget made the subject of child welfare the most outstanding part of his eloquent addresses on international health, it will be interesting to note what the recently issued report of the chief medical adviser to the British Ministry of Health has to say on the matter. I mentioned in a former letter that I should take several occasions to refer to this extremely valuable document which is distinguished by the solid facts it contains expressed in lucid and logical language. It is stated in the first instance that the health of the mother and child is obviously the primary step in the health of a community. For here is the source of a nation. It is almost true to say that, from a health point of view, what the mothers and children are the nation is and will be. It is then pointed out that immense progress has been made in this subject in recent years. The results of the various acts passed since 1907 have been very remarkable. The decline in the death rate of infants from 150 per 1,000 born in 1900 to 59 at the present time must be attributed in large measure to the action taken. It is one of the two or three most significant triumphs of preventive medicine in the present century.

The report then goes on to recount the steps which have been and are being taken to preserve the lives in good health of the women and children of this country. Among other measures, a scheme of maternity and child welfare has now been inaugurated in every county and county borough of England and Wales and in many of the larger urban districts. There are now (the report was written at the end of March of this year) in existence 1,754 maternity and infant welfare centers, 221 day nurseries or crêches, and 89 maternity homes with 1,360 beds. In many areas also the midwifery service is being reorganized and brought into closer association with other forms of maternity and infant health service. However, these services are, of course, not yet adequate or complete in the sense of solving the problem. The death-rate of women in childbirth remains approximately what it was 25 years ago, and there is lost by death every year upwards of 3,000 mothers in the fulfilment of one of their principal and most vital duties to the State, a mortality almost entirely preventable. Then in the next place there is a large volume of abortion, miscarriage, still-birth, and ophthalmia neonatorum, a very large part of which is directly avoidable.

Again, a substantial number of the 700,000 mothers who gave birth to children in 1919 were so injured or disabled in pregnancy or childbirth as to make them chronic invalids and bring them in very large numbers to the gynecological clinic or the hospital ward, an excessive burden of preventable invalidity, incapacitating in its immediate and deterrent in its remote effects. This is an issue which profoundly affects the woman as industrial worker, as home-maker and as mother. Lastly, there is still lost by death not less than 60,000 infants in the year, excluding 19,000 still-births. The four-fold problem, it is pointed out, can only be met by a wide, continuous and persistent effort in every district of the land, an effort which must be comprehensive and not confined to one or two methods. It must be concerned with the efficiency and adequacy (1) of methods for the supervision of pregnancy; (2) of midwifery; (3) of maternity homes and hospitals; (4) of home nursing and health visitation; (5) of infant welfare centers and institutions, and (6) of the sound administration and wise use of maternity benefit. No panacea will meet the situation; it can only be met by a comprehensive movement, universally accepted and steadily pursued. Then the final issue cannot be doubted. The State cannot afford to be careless or negligent of motherhood; it cannot afford to leave its infant life to chance or the misfortune of circumstance. There must come a time when civilization means that no child-bearing woman is without adequate and skilled assistance, and no infant without a birthright of health. In the opinion of the writer of the report that time should come in England first among all nations.

It may be said that concerted efforts are afoot to improve the conditions under which the great majority of women bear children in this country. Obstetrical work is performed mainly in the houses of the patient and amid surroundings not adapted in any respect as a lying-in room for a parturient woman, and still less for the performance of what would be probably a surgical operation. In fact, childbirth in itself is a surgical operation, while for abnormal pregnancy mechanical removal is the only specific treatment. Consequently, midwifery should be done under the best possible aseptic conditions and with highly efficient skilled aid. As is pointed out in the report there is a great dearth of maternity institutions in this country and until this deficiency is remedied lying-in mothers will die in unduly large numbers, be functionally and physically incapacitated and children will not be born in the healthy manner they should be.

Clinics for Mental Diseases.—The Lady Chichester Hospital for Women and Children at Hove, Sussex, the only hospital in Great Britain which specializes in all forms of nervous and mental

breakdown in their early stages, has published recently a short survey of its work during the past fifteen years. This publication points out that experience gained in the hospital strikingly confirms the arguments which the leading mental specialists are now urging in favor of establishing clinics for the treatment of such diseases in connection with the general hospitals. Under the present system no hospital treatment is provided for nervous and mental paients until they have reached the certifiable, and, therefore, in the majority of cases, the incurable stage. What is urgently called for is that sufferers from these diseases should have exactly the same prompt and easy access to treatment as those afflicted with any physical disease.

The survey analyzes a hundred consecutive cases which were treated at the hospital. They were of all ages, ranging from six to eighty-three, and came from all parts of the country and from many different occupations. Of the hundred no fewer than fifty-four were completely cured. While only twenty-two left the hospital without showing any improvement, and not one of the twenty-two was a genuine early case. Some of them had been suffering for years, and it is thought might have been cured if they could have been treated in time.

The war has given an impetus to the intelligent treatment of mental disorders of a certain class. As a matter of fact it is really rather preventive than curative treatment and follows on the lines laid down by Sir James Mackenzie's early diagnosis and treatment to prevent the malady from proceeding further. But in the case of mental disorders, it is especially essential to make a prompt and correct diagnosis and therefore the establishment of psychopathic wards in general hospitals, a plan, I believe, which is pursued in several large American general hospitals, is almost a sine qua non of successful treatment. It seems likely that when the great desirability of this plan is fully appreciated it will be widely adopted in this country.

A Radium Hospital in Manchester.—Sir Edward and Lady Holt have presented Nelson House Nursing Home, almost adjoining the Royal Infirmary and Eye Hospital, to the Manchester Radium Institute, as a hospital in which patients can be treated by radium and housed. The hospital will be handed over absolutely free from encumbrances and completely furnished and equipped. All the hospitals of Manchester together with Bury Infirmary, will participate in the use of the Radium Institute. The hospital just given will be the first in Great Britain to be used exclusively for treatment by radium. Also as there are thirty beds in the new hospital, patients will not be distributed among eight institutions as at present, although radium treatment, if necessary, will be carried on in these hospitals. Manchester has spent already nearly £30,000 for its stock of radium. Up to the present the institute has been self-supporting by means of fees paid by private patients. However, the upkeep of the hospital will necessitate the aid of the public if the fullest benefit is to be reaped from this gift.

2. Tuberculosis and Influenza. John B. Hawes, 2nd.
3. Traumatic Spleens. Francis Freeman Henderson.
4. Ruptured Uterus in Previously Caesareanized Patient. Charles J. Kickham.

1. Lessons from the Selective Military Draft.—Oliver H. Howe, from a review of this subject, points to certain physical advantages that would accrue should universal military training be adopted. The benefit of examinations like those of the draft would be further extended. In fact, he holds, a physical survey of the youth of the land would be made every year. This would undoubtedly stimulate the race to greater physical stability. The military training would eliminate the last tendency to round shoulders and would improve the physique as it uniformly did during the late war. Should certain measures which the writer suggests (medical inspection in schools, provision of hygienic conditions in schools, annual physical examinations of pupils, etc.), be carried out in the schools and in the homes. Following the general acceptance of the means of preventive medicine, the author expresses his belief that another generation will show a man-power that may be regarded without reproach—a physical perfection of which one may be proud.

3. Tricuspid Stenosis and Tricuspid Insufficiency.—Young and Cotter were prompted by the lack of specificity in the symptomatology of tricuspid disease, as usually described, to record the anatomical and clinical findings in a series of four cases of tricuspid disease, and to call attention to certain pulsatory phenomena in the liver, which they consider characteristic of certain lesions of the right side of the heart. From this study they are led to express the view that the most valuable clinical sign of organic tricuspid disease is the presence of a pulsating liver which continues to pulsate or even pulsates more markedly under influences calculated to effect disappearance of this phenomenon.

6. Cholesterol Thorax.—Joseph H. Barach discusses briefly the occurrence of cholesterin in the body and of cholesterinemia following obstruction to the free flow of bile into the intestines. In certain locations following the accumulation of fluid, if that fluid remains stagnant for a sufficient length of time, a deposit, or a crystallization of cholesterin, may occur. The fluid of cholesterol thorax may be mistaken for chylous or pseudochylous fluid if one were to rely upon the macroscopic appearance of the fluid. True chyle will show a fat content of about 10 per cent. and small fat globules, while pseudochylous fluid will have a fat content of about one-half of one per cent., and its fat globules are much larger. Whereas the chylous fluids are milky in appearance, the cholesterol fluids are more of the color of butter. In not one of the cases cited did the cholesterol deposit occur at the time of the primary attack upon the diseased part. The deposit or precipitation of cholesterin crystals occurred in inflammatory exudates within serous sacs, following the subsidence of acute inflammatory processes. The author notes that the cases cited show that the antecedent history of a deposit of cholesterol may vary from five years to as long as thirty years.

1. A Method of Treating Congenital Syphilis.—Fordyce and Rosen, in their work at the Vanderbilt Clinic, undertook to formulate, first, a method analogous to that employed in adults, i. e., to treat these patients intensively in the secondary stage, endeavoring to obtain a cure as quickly as possible, and, secondly, to make the plan workable and easy of application. In the method described, neoarsphenamine and mercury are used intramuscularly with a special needle to insure the proper location of the drugs in the gluteal muscles. If the infant is very much underweight, with a poor musculature, mercury alone is given at weekly or biweekly intervals until there is an improvement in the general condition, after which the injections of neo-arsphenamine are begun. The mercurial employed is the mercuric chlorid put up in palmatin in individual collapsible ampules in doses of from 1/10 to ⅛ grain or larger for older children. An ordinary mercury needle of from 19 to 20 gage, cut down to from one-half to one inch in length, is used. After the buttock has been sterilized with iodine, the injection is given into the muscle about one inch from the intergluteal fold near its upper angle. The neo-arsphenamine is put up in individual glass ampules containing from 0.1 to 0.2 gm., and large enough to hold 5 c.c. of solution, the object being to dissolve the drug in the original container. After the ampule has been immersed in alcohol to insure its proper sealing and sterilization it is dried with sterile gauze, the end broken off, and from 2.5 to 3 c.c. of cool sterile, freshly distilled water injected into it by means of a syringe. There is then attached to the syringe a Luer mercury needle long enough to reach the bottom of the ampule, and the fluid is drawn into the barrel, the solution being alternately expelled and drawn up to hasten complete solution. Infants, on the whole, tolerate drugs well; it is surprising what large doses can be administered with safety. The amounts given by the writers are large when computed according to the weight ratio, but so far no untoward results have arisen, and it may be possible to employ even larger doses. They are now giving neo-arsphenamine in the following doses at weekly intervals: 0.075 gm. for infants from 3 weeks to 8 weeks; 0.1 gm. from 2 to 6 months; 0.15 gm. from 6 months to 1 year; 0.15 to 0.2 gm. from 1 to 2 years. These doses are employed in courses of from six to eight, followed by rest periods of from four to six weeks. The histories of nine infants treated by this method are detailed.

7. The Causes and Occurrence of Functional Scoliosis in College Men.—William Lawrence Estes, Jr., in his capacity of consulting physician to Lehigh University, has had the opportunity to take part in the physical examination of the entering freshman class each fall from 1912 to 1919, with the exception of 1918. Early in the routine procedure he was struck by the surprising frequency with which a mild type of functional scoliosis was found. The men exhibiting scoliosis were consequently subjected to a more detailed examination with a view to determine the underlying causes. During the seven years 1856 men have been observed. Functional scoliosis was found in from 10 to 20 per cent. of the men of college age, the left-sided curve predominating (70 per cent.). This scoliosis results chiefly from flatfoot, occupational or developmental peculiarities, and from shortening in one lower extremity. This shortening may exist in Bryant's line, or in a trochanter to external malleolus measurement. A mild coxa vara, and variation in length of the femoral, and sometimes the tibial shaft, have been suggested as the most likely explanation of this shortening.

1. An Address on the Nature of the Ovarian Function and the Medical and Surgical Methods Adopted to Secure the Benefits of the Ovarian Secretions.—W. Blair Bell discusses the relation of the ovary to sex-characterization, the genital functions of the ovary, substitution and supplementary therapy, and ovarion grafting. Based on a fair experience, he advocates very strongly the practice of ovarian grafting in suitable cases. Nevertheless, he insists that this procedure be looked upon as a measure of necessity, which can never be weighed in the balance against the preservation of the natural connections of the normal ovary. While endeavoring, from an examination of the information at his disposal, to assign to the ovary its place in the economy of woman, he tries to make clear his belief in the sanctity of the task entrusted to those who deal with important living structures, knife in hand. The search after surgical knowledge is the search after better ways of assisting Nature to fulfil her purpose amid the manifold disharmonies of incomplete evolution. One has no right, therefore, wantonly to destroy. Rather must one strive to preserve intact and, if this be impossible, to foster or to substitute to the best of one's ability in imitation of the original design.

3. The Myth of "Atypical" Enteric Fever.—R. P. Garrow gives the personal experience on which he bases his "unorthodox" views. From July, 1915, to June, 1916, at the Military Infectious Hospital, Imtarfa, Malta, he observed upwards of 2000 cases of enteric or suspected enteric fever. As acting medical officer in charge of wards he had ample opportunities of studying the clinical, bacteriological and serological aspects of the enteric problem. This was followed by a similar experience of one year at the Military Infectious Hospital, Choubra, Cairo. He summarizes these observations as follows: 1. Enteric fever (typhoid and paratyphoid), far from being the "protean disease" it is usually represented to be, is remarkably constant in its clinical manifestations and true to type. This applies to the inoculated and uninoculated. 2. Enteric fever, whether in the inoculated or uninoculated, may appear clinically in every degree of intensity from extreme mildness to overwhelming severity. 3. "Atypical" enteric fever is a myth, in the creation of which two chief factors have operated, viz., (*a*) smallpox occurring in the vaccinated is so modified as to be frequently diagnosed as the milder disease, chickenpox. While that may be good reason for expecting that enteric fever in the inoculated should be similarly modified in *severity*, it does not support a belief that it is so modified in *character* as to resemble such divers diseases as malaria, trench fever and dysentery in their classical forms. (*b*) A far more important factor has been a lack of co-operation between workers in the wards and in the laboratory, and failure to co-ordinate their findings. When clinical and laboratory findings have conflicted the latter have prevailed, because laboratory investigation of disease has been generally regarded for

some reason to be more "scientific" than bedside observation. The truth, however, is gaining ground that science in medicine is not confined to the laboratory. The bedside has its victories no less than the bench. The flimsiest piece of evidence from the laboratory has often been accepted as proof of enteric infection in the face of bedside evidence which renders such a diagnosis untenable. The physician has thus allowed himself to be completely dominated in the matter of diagnosis by the pathologist. Diagnosis is the function of the physician; the pathologist's duty is to supply certain of the data for diagnosis. 4. Anti-enteric inoculation is the gift of practical bacteriology to preventive medicine, and is probably the greatest victory known to preventive medicine since Jenner's discovery of vaccination against smallpox. It would be a strange irony if the full fruits of this victory were lost amidst the clinical chaos resulting from the undue domination of bacteriology (and especially academic bacteriology) over clinical medicine.

1. An Address on Surgery—Good and Bad.—Charles F. M. Saint holds that in an ideal scheme for the treatment of disease, operative measures have no place, and the best surgery is that which approaches most closely to the ideal. Unfortunately, the present imperfect state of knowledge of disease, and consequent limitations so far as ideal treatment is concerned, leave open a wide field in which operative interference offers the best hope of cure to the patient. However, this interference is minimized by the surgeon of good judgment as unnecessary, and futile operations will be avoided. The failure of the natural and medical means of treatment has been postulated as the judication for operative interference, and it is just here where good judgment appears at its best. For whether or not operative measures will be necessary, what they shall be if they should be called for, and when the most opportune time will be for utilizing them, are questions which depend entirely on the adjudged efficiency or futility of the non-operative treatment. Pending the realization of this visionary ideal, however, the burden of present imperfection has to be borne, and a very prominent part in the treatment of disease must continue to be played by surgery, the basis of which consists of: 1. Good judgment, with all it involves—of paramount importance; and, depending on this—2. Rational treatment, non-operative or operative. When operative measures are indicated, then the outstanding features of good work are: (*a*) Conservatism consistent with efficiency; (*b*) simplicity of technique; and (*c*) operative skill, which includes gentleness, manipulative dexterity and careful speed.

1. Some Newer Concepts in Digitalis Therapy.—Cary Eggleston reviews the newer conceptions concerning digitalis in the treatment of cardiac disease, and sets forth the following plans of dosage by oral administration: *Small Dose Method.* From four to six days are generally required for digitalization by this method; ⅛ to ¼ gram (gr. ij to gr. iv) of the powdered leaf or 1¼ to 2½ c.s. (♏ xx to ♏ xl) of the tincture should be administered every four hours—four doses daily—and continued until digitalization is induced. With weak or poorly absorbed specimens of digitalis full digitalization may not be secured at all by this method or it may require ten days or more to secure it. *Large Dose Method.* From one to two days are required for digitalization. During the first twenty-four hours a dose of 4/10 gram (gr. vj to gr. vij) of the powdered leaf or 4 c.c. (dram j) of the tincture should be administered every six hours, day and night for four doses. On the second day the dose should be reduced one-half and the interval may be shortened to four hours, giving four doses per day and none at night. This latter dose and interval should be continued until full digitalization is secured. *The Body Weight Method.* This method permits full digitalization within ten to twenty hours from the beginning of administration and is specially serviceable in cases manifesting urgent symptoms. Its use has proved so satisfactory during the five years that have elapsed since its introduction that it has been possible very largely to do away with the necessity for the intravenous or intramuscular administration of ouabain, strophanthin or other digitalis preparation.

5. A Clinical Study of Wassermann-Fast Syphilis, with Special Reference to Prognosis and Treatment.—Stokes and Busman summarize their findings in this study as follows: 1. Of 458 syphilitic patients who had received from twelve to twenty-nine arsphenamine injections combined with mercurial inunctions, the average being fourteen injections and ninety inunctions in eleven months, 6.6 per cent. of primary and secondary cases and 101, 22 per cent., of latent, late and hereditary cases (average duration thirteen years) remained persistently Wassermann positive. 2. Cardiovascular changes are apparently those most likely to underlie a resistant positive Wassermann test in late syphilis (44 per cent.), with neurosyphilis 30 per cent., osseous lesions 30 per cent., hepatic, splenic, and gastric syphilis 21 per cent., and other types from 10 to 17 per cent. 3. More than one type of involvement was the rule in the individual cases of this group. There were only 10 patients presenting no other evidence of syphilis than their positive Wassermanns. 4. Patients with syphilis should therefore be studied from other angles than that of the presenting type of involvement, in the effort properly to appraise their condition and susceptibility to treatment. 5. Sixty-five per cent. of the patients with cardiovascular syphilis had aortitis and 60 per cent. myocardial changes. 6. Of the neuro-syphilitics, 40 per cent. had paresis and 50 per cent. clinical tabes dorsalis. 7. Fifty per cent. of patients with neurosyphilis had cardiovascular syphilis also. 8. Gastric and hepatic syphilis were recognized in 52 and 47 per cent. of the visceral cases as against only 14 per cent. presenting recognizable splenic involvement. Patients with cutaneous syphilis showed the familiar immunity from neurosyphilis and the reverse. 9. While pyogenic foci were present in 74 per cent. of the patients with resistant-Wassermann reactions no frank etiologic connection was apparent. The same was true of alcohol, which was used by only 12 per cent. of these patients. 10. There was no evidence that Wassermann-fastness is the result of infection with any special strain of organism. In fact, the "polystructural" involvement in such cases suggests the contrary. 11. Eighty-four per cent. of the patients in the Wassermann-resistant group

have undergone symptomatic arrest to-day under the treatment received. Paresis and tabes dorsalis with gastric crises formed more than half the failures. 12. The amount of treatment to which a Wassermann-resistant patient should be subjected cannot be exactly defined. The principles employed in making a decision, which are in effect the principles underlying the therapy of all late syphilis, are outlined. In particular, reversal of the Wassermann, while desirable, should not be the primary aim of the therapy. Symptomatic response, with arrest of the process, and the giving of as much treatment as to an early case, provided tolerance permits, are the important considerations. 13. A persistently positive serum Wassermann reaction seems to be an accompaniment of grave rather than of trivial syphilis. At least such is the case in enough instances to suggest the need for the most painstaking and repeated investigation of the clinical aspects of the Wassermann-fast case. Premature statements based on insufficient evidence as to the insignificance of a fixed positive Wassermann reaction are, they believe, to be deprecated. 14. Wassermann-fast patients should not, in their opinion, be discharged from periodic careful re-examination, with special reference to the cardiovascular and nervous systems throughout life. The frequency of such examinations should be dictated by the gravity and extent of the original process and the degree of apparent resistance to treatment.

11. The Gravity Resisting Ability of the Circulation; Its Measurement and Significance (Blood Ptosis).—C. Ward Crampton holds that the estimation of the ability of the circulatory apparatus is of considerable importance, both to the physiologist and to the clinician, and that the simplest way to test the circulation is to give it a standardized amount of work to do and to note its reaction to this work, estimating what is normal and what is abnormal by the character or extent of the reaction. The writer has suggested the use of a standardized load which may be imposed upon the circulation simply and easily and in an entirely natural manner. This consists in observing the reaction of the circulation to the hydrostatic load placed upon it when the subject rises from the horizontal to the vertical position. He discusses the rationale of the test; the conduct of the test, with examples; the gravity resistance in various diseased conditions, and physiological and other clinical variations of gravity resistance ability. The study is summarized as follows: 1. The horizontal and vertical blood-pressures may differ greatly in the same individual. 2. A rise in systolic pressure on standing indicates efficiency in the gravity resisting ability of the circulation; a fall, the reverse. 3. The increase in heart-rate on standing indicates inefficiency in the gravity resisting ability of the circulation in proporton to the increase. 4. Taking both influences into consideration, an index may be determined for convenient use. 5. This index is lowered by various influences among which are fatigue, toxins, the approach of disease and disease itself. 6. This index may be high in good health and also in some disease conditions. 7. The index may prove helpful in estimating the extent illness is damaging the circulation in the course of disease and in estimating the progress of recovery. 8. This index may indicate the fatigue and the variations of condition in an athlete. 9. The normal range of this value is approximately from 50 to 100, although records in this range may be given by sick persons, but high records in sick persons are probably evidences of pathological overtone. 10. Records below zero are evidences of great lack of circulatory power. 11. Comparison of records of two individuals may or may not give much information. Successive records on the same case may give more. 12. The customary single recording of the blood-pressure in one position gives no information as to the gravity resisting function of the circulation.

October 14, 1920, xxxiii, 42.

Prearteriosclerotic Emaciation.—Kiralyfi of Professor Koranyi's Budapest Clinic discusses this phenomenon at some length. Emaciation commonly results from insufficient aliment and poor utilization, both factors being often conjoined in the same subject. The sudden and extreme loss of weight which sometimes supervenes before the development of arteriosclerosis may reach 60 pounds. Examination for a cause is attended with practically negative results and the only factor in evidence in some cases was defective calories from war privations. There could be no mere coincidence between presclerosis and emaciation. The age period was 45-55, when arteriosclerosis commonly begins. During the process of emaciation the subject may appear to be in the best of health. Ordinarily, when losing weight, the individual complains of a train of symptoms which comprises malaise, dizziness, depression, and fatigue which supervenes rapidly on exertion. The condition cannot be due to war factors, or at least the author was familiar with it before the outbreak of hostilities. It appears to be readily controlled by supernutrition. The diet should be rich in calories and be well balanced. The only drug recommended is iodine, the too protracted use of which may, itself, lead to loss of weight. The author is not clear as to the diet of these subjects when the loss of weight begins, but inferentially the appetite was normal and in some cases at least the food intake as well.

2. The Value of the "No Good"—Alcohol versus Phenol.—Douglas H. Stewart emphasizes the point that "solvent" and "antidote" are not synonymous terms, and that a fatal issue to some patient may be forefended, at times, if the difference between the two terms is very clearly understood.

La Médecine.

September, 1920, i, 12.

The Biological Movement During the War.—Gautrelet, who edits the biological number of this new journal enumerates the following activities: use of vaccines to combat epidemics, sterilization of water, grafts to replace lost tissues, blood studies, a great variety of studies of the nervous system and cerebrospinal fluid, cardiac studies with special reference to oscillometry, parasitology, radiations, etc., etc. To take up a special subject, that of wound healing, the author first seeks to know how wounds become infected in wartime? The elements he considers in succession are traumatic shock, and incidentally its prevention and treatment, the presence of germ carriers, the role of stinging insects and that of sensible parasites, the part played by special bacteria, including anaerobes, and the use of antiseptics. He then passes to the subject of alimentation of soldiers. In summing up he states that for the first time the different types of biologists have cooperated. The author uses the term in the widest sense of a savant who works with living organisms as distinct from those whose efforts are directed only to the inanimate world. These divisions of biology have a practical side also and should all possess their own special laboratories. But there is a great dearth of the latter as shown by the military needs. From another angle biologists assist the physician and surgeon; the latter of course may be themselves deserving of the term but in all practical activities such as prosthesis of limbs, aviation, gasing, etc., laboratory men and experiment were required and it is men of this type who supplement the practitioner that the author would designate as biologists, no other term being available.

Suprarenal Virilism.—Thirty cases of this affection have now been reported. One of the latest is by Mauclaire. A woman of thirty-eight developed an abdominal tumor a little to the right of the median line, and at the same time the menses ceased. The facies then changed and hairs appeared on the face, neck, and thorax. The subject increased in stature, the breasts atrophied, the muscles developed, and the panniculus receded. The diagnosis was at first ovarian cyst, and only during the operation was the correct diagnosis made. After removal of the tumor, ovarian extract was given and the menses returned.—*La Tribune Médicale.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 26, 1920.

DR. HAROLD BAILEY IN THE CHAIR.

Pudendal Hernia, Operated by the Abdominal Route.—Dr. JAMES F. GRATTAN reported this case, which occurred in a woman 53 years of age, who complained of irritation in the rectum with difficulty in moving the bowels and a bearing down sensation in the vagina, ascribed by two physicians who had examined her to "falling of the womb." With the examining finger in the vagina, the patient was told to hold her breath and strain downward. She was then told to cough. As she repeated the cough the speaker thought he felt an impulse against the back of his examining hand. A repetition of the cough revealed a definite impulse in the adductor reigion of the left thigh. A mass the size of a hen's egg developed at the site of the impulse. The mass was soft, reducible, and gurgling occurred on manipulation. The location was a crescentic area external to the left labium majus, but not involving that part. It was evident that the patient had a hernia. At operation an incision extending from the symphysis to the umbilicus was necessary on account of the extremely fat abdominal wall. Exposure of the pelvic organs, though difficult, was finally accomplished and revealed descent of the sigmoid loop through a triangular opening in the floor of the pelvis. This opening was bounded anteriorly by the posterior reflexion of the broad ligament, mesially by the lower segment of the uterus and the left uterosacral ligament, literally and posteriorly by the rectum. The sigmoid being fixed at its point of continuation into the rectum appeared to slide down along the posterior surface of the broad ligament and disappeared into the hernial opening. There were no surface adhesions and no evidence of constriction of any point. Gentle traction brought the sigmoid loop out of the sac. There was no process of the sac descending into the left labium, as in the cases of "pudendal" hernia reviewed by Moschcowitz. However, the exit and course of descent in this case was undoubtedly the same, the final destination being the subcutaneous tissue of the upper adductor region of the thigh rather than the labium. The protrusion undoubtedly occurred through the levator muscle and passed through the triangle bounded externally by the ischiocavernosus, internally by the constrictor cunei and posteriorly by the transversus perinei, then along the left lateral wall of the vagina, emerging in the thigh. The split in the levator was probably the result of a difficult twin labor mentioned in the history. No attempt was made at extirpation of the sac, since its depth, the adipose status of the patient and her age precluded the needless prolongation of the anesthesia. Five or six stitches of double pagenstecher linen were placed across the long arm of the triangle, thus closing it tightly and completely. A continuous suture was then whipped over the line of mattress suture, taking another reef in the broad ligament. This last step caused a version of the uterus backward and to the left, superimposing the fundus over the site of the hernia opening. The sigmoid was anchored to the left psoas muscle at the brim of the pelvis and about two inches above that point, the idea being to prevent its descending to its habitual location in the neighborhood of the hernial opening. The abdomen was closed in the usual way. The patient made an uneventful recovery and remained free from recurrence during the two years that she was under observation. Dr. Grattan said he reported this as a case of pudendal hernia because he felt sure that it corresponded to the cases of pudendal hernia described by Cooper in his volume on hernia published in 1807, and to the cases collected, under the heading of pudendal hernia, by von Winckel, in 1881, and reviewed by Moschcowitz. Moschcowitz called attention to the question whether it was a fallacy to name this hernia for its destination (the vulva) rather than for its point of exit in the pelvic floor. The present case demonstrated this fallacy because the destination of the sac happened to be the adductor region of the thigh rather than the pudendum. Dr. J. A. Blake suggested the term "levator hernia," but the speaker said he felt that he was not justified in making a new classification for a hernia the course and surgical anatomy of which was essentially the same as in the cases described under the term "pudendal" hernia. According to Moschowitz no case of "cure" of this type of hernia was recorded. This patient had been two years without recurrence, during which time she had been performing the heavy work of her household.

Dr. WILLIAM P. HEALY congratulated Dr. Grattan upon his careful examination of the case, for the condition was such that it could easily have led one into error, and upon the correctness of his diagnosis depended the cure. He was also to be congratulated on his excellent surgical result. The condition was so rare that few had seen a hernia at the vagino-labial base. Such a hernia might come out anteriorly or posteriorly, appearing in the labial crease. When this occurred the hernia was likely to be looked upon as a rectocele instead of a true vagino-labial hernia. One occasionally met such a case in which a colporrhaphy and plastic operation was done, but not being a true rectocele the hernia was not reduced and went through the cul-de-sac of Douglas and out over the required pelvic floor. The best way to deal with these cases was as Dr. Grattan had done. If possible reduce the sac. Having turned the sac inside out into the peritoneal cavity excise it. The hole could then be obliterated and the neck of the sac reinforced with such structures as were nearby. There need be no fear of these hernias undergoing obstruction or strangulation for most of them had very free access into and out of the hernial canal.

Dr. HAROLD BAILEY thought the point Dr. Grattan made about the name was very important. If the cases of true pudendal hernia were those that ruptured into the vagino-labial fold, he thought it would be well to differentiate between this type of hernia and one such as Dr. Grattan had described, which gradually came down into the adductor region of the thigh.

Right Tubal Pregnancy—Fourth Month with Rupture Into the Cecum.—Dr. HERBERT C. CHASE reported this case by invitation. He said his reasons for reporting the case were the clear sequence of events which led to a fairly easy diagnosis, and his belief was that the condition is exceedingly rare, as he could find nowhere in the literature its exact duplicate. The patient, 25 years of age, began bleeding on May 4, after having missed February, March, and April. The flow was scant, accompanied by no pain or clots. On June 20 she began vomiting and experienced knife-like pains in the lower left quadrant of the abdomen. The pain continued until August 7, when she felt a strong desire to evacuate the bowels. Several efforts were made but with no result until midnight of the same day, when she passed by rectum a large amount of dark clotted and bright red blood. From this time until her admission to the hospital on August 14 she had no pain but was very weak and much of the time did not know what was going on about her. When first seen she was pallid, emaciated, colorless; her pulse was thready, heart sounds weak with a soft systolic murmur at the apex. The abdomen was flat and soft. A mass the size of a fist and easily palpable was felt in the right side of the pelvis. Vaginal examination negative; the uterus was normal in size and position; the left adnexa were negative. She was at once given an infusion of 500 c.c. and brought by ambulance to the Woman's Hospital, arriving at 1 A. M. Here she was given a direct blood transfusion, which was followed by a marked improvement in the blood count. She lost no more blood, and at 8.30 A. M. seemed better. It was then decided to open the abdomen. A median, vertical, suprapubic incision was made. There was no bleeding or fecal matter, or any soiling of the peritoneal cavity. The omentum and several loops of the intestines were adherent to the posterior surface of the right tubal mass. The cecum was adherent to the posterior surface of the ruptured ectopic, and when it was separated a hole in the gut wall the size of a silver dollar was seen. The lumen

of the gut was filled with a large round clot the size of an English walnut, which filled the annular opening and was adherent to the posterior surface of the ectopic mass. When this clot was lifted the fetus lay in the cecum. There was no other rupture and no blood in the cul-de-sac or pelvis. The remainder of the large intestine from the secum to the sigmoid was filled with blood clots. The rent in the cecum was repaired with a continuous suture of zero chromic catgut for the mucosa and a continuous Lemoert suture of fine pagenstecher for the serosa. The ectopic mass was then quickly removed after ligation of the blood vessels, and a posterior vaginal drain of one inch iodoform gauze was introduced through the vagina from above down. During the operation, which required forty minutes, the patient was given 500 c.c. glucose into the vein. She reacted well after the operation, but on the fourth day it was deemed advisable to give her a transfusion. Following this she gained rapidly, was out of bed on the fourteenth day, walked on the seventeenth day, and went home on the twenty-first day. On October 17, her blood pressure was 112, hemoglobin 58 per cent., and her general condition had improved so that she was able to do her own housework. The pelvic examination was negative. The pathologist's report describing the specimen was presented.

An Analysis of Fifty Cases of Ectopic Gestation.—Dr. HERMANN GRAD made this contribution, in which he divided ectopic gestations into four groups: 1. Ectopic gestation with negligible hemorrhage. 2. Ectopic hemorrhage with moderate hemorrhage. 3. Ectopic gestation with severe hemorrhage. 4. Ectopic gestation with fatal hemorrhage. Of the 50 cases reported, 37 were of the first group; 4 of the second; 7 of the third, and 2 were of the fourth group. Charts were presented showing that in the first group only 25 per cent. of the cases were diagnosed, while in the second group 50 per cent. were diagnosed. In the first group pain was the most common symptom in three cases and bleeding in one. In the third group collapse was the prominent symptom. It would seem that there was little difference between a case with collapse and one with syncope, but actually there was a great difference. In collapse the patient had a thready pulse but her mind was clear; she was alert and conscious of everything. It was different in a case of syncope; here the patient's mind was dull and she was not conscious of what was going on about her. Her pulse was lost. He felt that he could hold out hope for ruptured ectopic cases in collapse, but there was little hope for one in collapse with syncope. A chart showed the various operations performed on the 48 cases operated upon, and also that gestation occurred with the same frequency in both tubes. Patients belonging to the first group frequently recovered spontaneously. If the hemorrhage was discovered operation should be performed because there was danger of repeated hemorrhage. Operation could be deferred until the peritoneal irritation subsided. The problem was different in the third group of cases. In these shock was very great and collapse imminent. These cases required immediate treatment even before they were transported to the hospital. Local manipulations of every kind should be avoided. All efforts should be directed toward supporting the vital functions of the patient until the hemorrhage could be controlled by operative measures. The pain should be relieved by morphine, the head lowered, the extremities bandaged. A donor should be procured for a blood transfusion, which was started before the incision was made in the abdomen, continued during the operation, and ended when the abdomen was closed. Could anything be done for the fourth group of cases? These fatal cases of hemorrhage bore transportation poorly; therefore something must be done for them when they were first seen. The first aim in these cases was to restore the circulation to a degree compatible with life. Infusing these patients with saline to which 6 per cent. gum acacia had been added would restore the circulation for a short time until the patient could be transported to a hospital where the bleeding could be stopped and a transfusion given from a proper donor. A physiological salt solution did not remain in the circulation long enough to do any good, but by adding gum acacia the fluid remained in the circulation for a longer time.

Dr. FRANK R. OASTLER said he had had the privilege of seeing 150 cases of ectopic gestation, the last that afternoon. In looking over Dr. Grad's paper, the first thing that was noticeable to him was that Dr. Grad called attention to the fact that ectopic gestation was really a subacute disease. Out of 109 cases which he had reported in 1917, in *Surgery, Gynecology and Obstrics*, only 15 cases were of the pyrotechnic or explosive variety. The disease was for the most part subacute and not acute. It was the exception and not the rule to find the patient in a faint, collapsed, exsanguinated, and with a thready pulse. Another point upon which Dr. Grad's experience coincided with his was that ectopic gestation occurred the same number of times on the right as on the left side. When one considered the etiology of ectopic gestation a common cause given was inflammatory disease. Inflammatory disease occurred oftener on the left side than on the right side. If it was true that ectopic gestation occurred equally as often on one side as on the other, inflammatory disease might be a cause of ectopic gestation but it could not be the only cause. Dr. Grad divided his cases into four groups, the mild, the severe, those with collapse, and those with syncope. He had not been able to divide his cases so finely, but divided them into two groups, the fulminating and the subacute. If one made such a fine distinction the patient might leave us while we were making the differentiation. Dividing ectopic gestations into two groups made differentiation much simpler. Dr. Grad had attributed fatalities to hemorrhage. Dr. Oastler said he thought they might be attributed to shock as well as to hemorrhage. Dr. Grad said there was a lack of necessity of removing blood clots from the abdominal cavity. He would remove the blood clots from the abdominal cavity as thoroughly as possible because he believed they created shock in ectopic gestation. They made convalescence much harder and recovery much slower. He thought nearly all fatal cases were due to both hemorrhage and shock, but there was one class of ectopic gestations that was nearly always fatal, that was the interstitial variety. When one met with the fulminating cases that died before they reached the operating table it would be found that they were nearly all of the interstitial variety. Another question was the advisability of operating upon every case immediately. If one felt that he had made a diagnosis of ectopic pregnancy he should at least open the cul-de-sac and if he found blood the operation should be completed above or below as the case might be. As to the question of salt solution with glucose gum, he had had experience with salt solution but not with glucose gum, and was not yet converted to the idea that salt solution was useless. He considered it a procedure of value, for it must be remembered that one could not always obtain blood for transfusion. Furthermore a reaction might follow blood transfusion which might be sufficient to topple over a patient who was on the verge between life and death.

Dr. LOUIS J. LADIN stated that he was absolutely in accord with Dr. Oastler on every point upon which he took issue with the reader of the paper. He had repeatedly laid stress on what Dr. Oastler had said in papers he had published and in discussions on this subject; and was glad of the opportunity to emphasize these facts again. Dr. Grad's grouping was original and interesting, but he believed the only safe classification of tubal pregnancy was the division into two groups—ruptured and unruptured. He could not understand why a correct diagnosis was made in only 25 per cent. of the series. This was certainly much too low a percentage. A positive sign of intrauterine pregnancy was the elastic area in the median line of the anterior wall of the uterus, to which he had called attention in a paper read before this Section in February, 1907. In uterine pregnancy the elastic area was always present. As regarded treatment, after all that had been said and written on the subject it was indeed surprising to find an advocate of delayed operation, especially in this city, where transportation and access to a hospital could be obtained at a minimum loss of time. His experience consisted of a series of over three hundred operations for extrauterine pregnancy, a large number of them being of the tragic type where

immediate operation was the invariable rule. No case was refused operation so long as there was a cardiac beat. There were four deaths in this series due to complications and not to shock and hemorrhage. In view of these experiences he had no hesitancy in saying that if the fatal cases reported by Dr. Grad had been operated on immediately upon arrival at the hospital, and infused or transfused afterward, instead of being infused or transfused while delaying the operation, the results would have been different. It could not be emphasized too strongly that shock, no matter how severe it might be, was no contraindication to immediate operation. Saline infusion should be employed either at the time or after the abdomen was open to check the bleeding. He had never had occasion to give a transfusion for hemorrhage from ruptured tubal pregnancy. It was generally admitted now that patients did die of hemorrhage due to ruptured tubal pregnancy, and he had seen one death caused by delayed operation. This patient collapsed in his office after examination, and instead of sending for an ambulance at once he waited for an hour or more before doing so. This was at a time some years ago when the doctrine of deferred operation was making its strongest impression. Prompted by that impression and actuated by a desire to avoid a scene in his office, he momentarily departed from his rule of immediate operation. When he did summon an ambulance there was some delay. He had the patient transferred to the nearest hospital, where she died on the operating table. This patient's life would have been saved if she had been transferred to the hospital at the time she collapsed in his office. Subsequent to that experience he had had four other patients collapse in his office with internal hemorrhage due to ruptured tubal pregnancy, and having learned his lesson, they were all immediately transferred to a hospital for immediate operation, and they all recovered. It was his practice to remove all blood clots from the abdomen, and as much as possible of the fluid blood. Clots might become infected and give rise to intestinal adhesions and interfere with the smoothness of convalescence. Shock and the rapidity of the recovery after operation depended not so much on the amount of blood as upon the time the hemorrhage was allowed to continue. The earlier the operation after rupture, the more rapid the recovery regardless of the severity of the hemorrhage.

Dr. BAILEY said he hoped the question of the advisability of immediate operation when the patient was in shock would be discussed. Under the conditions met in the war zone, as he understood, in the cases injured at the front it was found that the mortality was much lessened if measures were instituted to combat shock before an operation was entered into.

Dr. EDWARD WALLACE LEE said that several years ago he was called to see a patient in a hospital on account of a fibroid tumor which was growing rapidly. One of the features of this case was that the woman was having bloody discharges from the bowels, the blood being in clots that looked like old clots. The patient was 45 years of age and the tumor about the size of a six months pregnancy. On external palpation it did not give the feeling of a fibroid; it was somewhat nodular but not like a multiple fibroid. Vaginal examination showed fulness in the cul-de-sac. A sound passed into the uterus showed the uterus of normal depth. Without deciding upon the diagnosis he proceeded to open the abdomen. He found an immense organized clot of blood but no membranes. He broke off the clot piece by piece until he came down upon the Fallopian tube, near the ovary, and found where the clot came from. A portion of this clot seemed to run into the intestinal canal. It had evidently ulcerated through into the bowel. Further proof of this seemed to be offered by the fact that when the clot was cleansed away from the intestine the smell of gas from the bowels was very perceptible. He could not find the opening into the intestinal tract and did not look long for it, but drained and packed the wound and sewed up the abdomen. A fecal fistula resulted, which persisted for about six weeks and then closed. The patient's recovery was otherwise uncomplicated. This was evidently a tubal pregnancy. Dr. Grad's classification and treatment required a great deal of thought before one could coincide with all the views he expressed. First, he would speak of the cases of tubal pregnancy that were recognized when they came to the office, and in which an examination was made in order to differentiate them from pyosalpinx or salpingitis. These cases required operation but perhaps not immediately. Dr. Grad's so-called fatal cases demanded immediate operation before anything else was done; one should not even wait for a general anesthesia; local anesthesia could be used and no stimulation until hemorrhage was controlled.

Dr. HIRAM N. VINEBERG said that in reference to Dr. Chase's case, he recalled a case of ectopic pregnancy with hemorrhage from the bowel. In this instance the pregnancy had formed in the small stump of the tube following a salpingectomy for pyosalpinx some time before. The ovular sac was bounded in part by a portion of the sigmoid. At the operation he could not find any opening in the bowel. Evidently the villi had eroded the wall of the intestine sufficient to produce bleeding, but not enough to cause a defect perceptible to the naked eye. Regarding Dr. Grad's clinical classification of ectopic pregnancies, it might work satisfactorily in many cases, but a case with negligible intraperitoneal hemorrhage to-day might have a fresh infusion of blood into the peritoneal cavity during the night and to-morrow belong to one of the other groups. It was sometimes difficult to differentiate between the syncope due to shock, caused by the impact upon the peritoneum of a moderate amount of blood and that due to a very copious effusion of blood such as occurred in the class of cases grouped by the reader of the paper as *fatal*, and designated by the speaker as cataclysmic and by others as tragic. Dr. Vineberg said he found the following good working rule. In the moderate effusions an intravenous saline injection would bring about a prompt improvement which would be maintained; in the other group, there might be a slight improvement in the pulse at first, but it soon disappeared. The latter group (cataclysmic) were exceedingly treacherous. In one instance in which he was curetting a woman in her home and was not provided with instruments for an extensive operation, he opened the abdomen with scissors, stopped the hemorrhage and the patient recovered. When patients were in a desperate condition, he would not transport them but would operate at once even with the patient in bed. If a person cut the femoral artery he did not think of giving him saline and gum solution; if one was going to save the patient he could not wait for transportation or blood transfusion. Dr. Vineberg also corroborated the statement of Dr. Oastler and Dr. Ladin in reference to salt solution; it had helped him out in these very desperate cases. When the bleeding had stopped salt solution was a great help. If possible blood clots should be removed; it was not a good thing to leave them.

Dr. MEYER R. ROBINSON, after complimenting Dr. Grad on his paper and expressing admiration for his frankness in stating that in 25 per cent. of these cases he had failed to make a diagnosis, said the experienced clinician would readily understand this apparently large percentage of mistaken diagnoses. While the acute, fulminating and tragic cases of ruptured tubal pregnancy presented but slight diagnostic difficulties, the chronic cases would frequently task the diagnostic acumen of the most astute gynecologist. He was sure most of the diagnostic errors in Dr. Grad's series occurred in the latter group. At the Beth Israel Hospital where the number of ectopic gestations operated upon exceeded that of any other hospital in the city, they recognized only one contraindication to operative procedure in a case of ruptured tubal pregnancy and that was a dead patient. As long as the precordial heart sounds were audible and respiration was still present they operated, and not until sounder facts and better operative results were offered by those who waited for the symptoms of shock to subside before they resorted to operative treatment would they deviate from their rule of immediate operation. Why should intraabdominal hemorrhage due to ruptured tubal pregnancy be treated differently from intraabdominal hemorrhage due to other pathological causes? No other surgeon hesitated to stop hemorrhage as soon as it was diagnosed, why should the gynecologist hesitate? If shock was the deterrent

factor which stayed the hand of some gynecologists from carrying out their life-saving operation, then why resort to other means first instead of at once removing the cause of the shock, which in this instance were the hemorrhage and the peritoneal irritation by the foreign body, the free and clotted blood? As to the time of the transfusion he also took a very decided exception to the views of the reader. No intravenous infusion, no matter what it was, should be given before the bleeding point was secured. Nature in her effort to save the bleeding patient from exsanguination slowed the heart action, diminished the rate of the blood flow, and with the fibrin ferment formed as soon as blood was spilled produced clotting. The introduction of fluids into the veins stimulated the heart, increased the rapidity of the blood current, retarded clotting and thus thwarted nature's effort to keep the bleeding point plugged. Intravenous infusions in these cases was life giving and life saving if done after the bleeding had been stopped.

Dr. MAURICE OLIVER MAGID said most of the speakers had spoken only of the pathology and treatment of ectopic gestation. Dr. Grad maintained that ectopic gestation was a subacute condition and his view was confirmed by Dr. Oastler. As long as this state of the disease existed there must be some etiological features that could be controlled. He would like to hear what the gentlemen present considered the true etiology of ectopic pregnancy. Dr. Oastler made the point that inflammation was present but it was not the real or only cause of this condition. Everybody admitted that a diseased tube was the fundamental factor that must be present in every ectopic pregnancy. He would like to hear why the tube was diseased, and why the fecundated ovum could not leave the tube.

Dr. Grad said the case of Dr. Chase's recalled to his mind a similar condition. The patient began to bleed from the rectum before there were any symptoms of ectopic pregnancy. The blood was sometimes dark, sometimes brighter. The ectopic had ruptured into the rectum. He found evidence of a large pelvic abscess. The cul-de-sac was opened to drain and through the opening there extruded a small fetus.

Dr. CHASE said the point brought out in his case report was that the rupture was directly and primarily into the gut. There was no blood in the peritoneal cavity. Women were sometimes brought into the hospital in whom rupture had taken place into the peritoneal cavity which was followed by sloughing of the membranes and infection which gave very definite symptoms, but here the entire tube became distended and ruptured into the intestine, so that every bit of blood was lost directly into the intestine and through the rectum.

Dr. GRAD, in closing the discussion, reiterated the distinction he had made between collapse and syncope, and said that in the latter condition he questioned whether the patient could be saved whether one operated at home or took the patient to the hospital. The question was could anything be done to save these patients? Could something be put into the circulation that would sustain the patient until she reached the hospital where a donor could be obtained, a transfusion given, and operation performed. There was a difference between the shock of ectopic pregnancy and that seen on the battlefield. In dealing with ectopic pregnancy one must treat the condition of collapse. These patients died while they were being transported to the hospital. If gum solution were introduced it might be possible to save some of these patients. He had made a different classification of ectopic pregnancy from that they had been using because he felt that they had not dealt with this condition as efficiently as they should have done. The cases Dr. Ladin saved were those with severe hemorrhage, and when severe hemorrhage occurred such cases could be operated upon, but the type of cases he was speaking of were those on the verge of death. Here the question was not to stop bleeding, for that had already stopped, but to bring the patient into a state in which she could be operated upon. There had been some difference of opinion in regard to the removal of blood clots from the abdomen. He always removed as much of the blood as he could remove in an expeditious manner, but he felt that a blood clot would not do as much harm as prolonging the operation. A blood clot in the abdomen might cause a rise in temperature but it did not delay recovery.

Dr. LEE asked Dr. Grad if he thought that a blood clot left in the abdominal cavity could be of any benefit to the patient.

Dr. GRAD replied that blood left in the abdominal cavity was absorbed too slowly to do any good; he thought they could do no more damage by keeping the abdomen open longer to clean out the blood clots than we did in leaving some in. The question was, when called into consultation in these cases that were usually fatal and where they were practically helpless, whether there was nothing to be done but what they had been doing.

A New Method of Vesical Anesthesia.—Dr. HENRY DAWSON FURNESS made this presentation. He stated that anesthesia for cystoscopic examination and operative treatment of the bladder, aside from that obtained from general inhalation anesthesia, or nerve blocking, as in sacral, epidural, and spinal, had been most unsatisfactory. Some months ago Dr. Howard Lindeman had read a paper on the treatment of trigonitis by the injection of the trigonum with a solution of urea and quinine hydrochloride, and had exhibited a long needle which could be passed through a cystoscope to accomplish this purpose. In the discussion of Dr. Lindeman's paper Dr. Furness had recalled that he advocated the use of this instrument for the injection of anesthetic solutions into the base of ulcers to be cauterized, and also into the pedicles of papillomata to be fulgurated. Later it occurred to him that in women the same result might be obtained by a more simple method, namely, infiltration of the vesicovaginal septum from the vaginal side. This method was applicable, of course, only to favorably situated lesions. Almost any portion of the vesical wall could be infiltrated by one or both of these methods, although he would hesitate to infiltrate that portion of the bladder wall covered by peritoneum; yet in the absence of infection, even this portion might be safely and successfully anesthetized. He had recently had opportunity to operate upon three patients under infiltration anesthesia. Two of them had papillomata of the region of the ureteral orifice, and one had an ulcer over the trigonum. The two papillomata cases were successfully fulgurated with very little discomfort after infiltration of the portion of the vesico-vaginal septum that underlay the growth. In the ulcer case, cauterization with fused nitrate of silver was done almost painlessly. Previously he had cauterized the ulcer after having attempted to anesthetize the bladder by the instillation of 4 per cent. eucaine solution, but the procedure caused a great amount of pain. In each of these cases ½ per cent. solution of novococaine with adrenalin was used, the amount varying from 5 to 10 c.c. It was essential to have a tightly fitting plunger to the syringe, as otherwise there might be a back leakage and failure to deposit the solution in the tissues. The syringe used by dentists for the infiltration of gums worked admirably. Thus far, Dr. Furness said, he had used this procedure only in the cases mentioned but with each one the result was eminently satisfactory. He saw no reason why the whole mass of the bladder or any portion of it, could not be anesthetized, and any operation that could be done under general anesthesia (where the element of relaxation was not essential) might be performed. In none of these cases was any untoward result noted.

Dr. HOWARD E. LINDEMAN expressed the opinion that for the purpose mentioned Dr. Furness's method was much simpler than the one he had been using in the treatment of trigonitis. But his object was not to obtain anesthesia. In trigonitis the outstanding feature was the congestion, hypertrophy, and hyperplasia of the subepithelial blood vessels, and he attempted to cause a destruction or at least a constriction and compression of these vessels. Knowing that quinine and urea solution when injected into the tissues for the production of local anesthesia caused a deposit of fibrin and a considerable induration at the point of injection, he decided to employ this in the treatment of trigonitis, avoiding necrosis. He had never made the injection from the vaginal side, but believed this could be done by having a cystoscope in the bladder at the

same time to watch the point of the needle and control its location, and see that the point did not come through the mucous membrane, because one wished to deposit the solution in the submucous tissues. It might be simpler to give the treatment in this way, because it was not an easy procedure through the cystoscope and took considerable time; to cover an area the width of the trigone and for a distance of one-half an inch from before backward took one-half hour or more, but he believed it would be more difficult to localize the injection in the trigone unless a cystoscope were used coincidently in the bladder to control the site of injection.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

WEST VIRGINIA STATE BOARD OF HEALTH

July 13, 1920.

(*Concluded from page* 882.)

SURGERY.

1. Describe femoral hernia and give radical operation and details.
2. Give diagnosis and treatment of early carcinoma of the cervix.
3. Describe briefly the common symptoms of intestinal obstruction and the best methods of treatment.
4. What is cellulitis; give treatment.
5. Give symptoms of enlarged prostate and advise best form of treatment.
6. Differentiate toxic from simple goiter, and give treatment.
7. What are the causes, and give treatment of hepatic abscess.
8. Give treatment of a compound fracture of the rib.
9. Describe Colles' and Pott's fractures.
10. Give your treatment of a compound fracture of the lower third of the femur.
11. Give treatment for postoperative shock.
12. What is sepsis, and give treatment.

SPECIAL MEDICINE.

1. Describe the mechanism of accommodation.
2. Give cause, symptoms, and diagnosis of iridocyclitis.
3. Give cause, symptoms, and treatment of blepharitis marginalis squamosa.
4. Give signs, symptoms, and treatment of acute suppurative otitis.
5. Describe fully the rational treatment of aural polypi.
6. What is tinnitus aurium and its direct cause?
7. Give signs, symptoms, and treatment of antral sinusitis.
8. Under what conditions should the nasal turbinates be removed.
9. Causes and treatment of epistaxis.
10. Describe fully the clinical diagnosis between acute follicular tonsillitis and diphtheria.
11. Causes, signs, symptoms, and treatment of chronic pharyngitis.
12. Causes, signs, symptoms, and treatment of Vincent's angina.

ANWSERS.

SURGERY.

1. "A *femoral hernia* protrudes through the crural canal, and presents through the saphenous opening. It is more common in women, especially in those who have borne children. The coverings are: (1) Skin and subcutaneous tissue, (2) cribriform fascia, (3) anterior layer of the femoral sheath, (4) septum crurale and extraperitoneal fat covering the peritoneal sac. The femoral vein lies immediately to the outer, and Gimbernat's ligament to the inner, side of the neck of the sac. An irregular obturator artery may pass between the neck and the femoral vein ,or along the free border of Gimbernat's ligament. A femoral hernia, after leaving the saphenous opening projects upward and outward along Poupart's ligament, and may even project above it, but the neck is always below Poupart's ligament and outside the pubic spine."—(*Aids to Surgery.*)

Radical Cure of Femoral Hernia.—An incision is made parallel with Poupart's ligament; the coverings are divided and retracted so as to expose the sac which should be cleared from the surrounding fat right up to where its neck disappears under Poupart's ligament. The sac is opened and any adherent omentum tied off and removed. The neck of the sac is exposed above Poupart's ligament by a small incision through the aponeurosis of the external oblique, and the sac is brought out through this, and its neck occluded and fixed by sutures. If omental adhesions extend above the level of Poupart's ligament, they are more easily dealt with if the ligament is cut across and the sac laid open throughout its extent. The opinion is gaining ground that no attempt should be made to close the femoral canal.—(Thomson and Miles' *Manual of Surgery.*)

2. *Early carcinoma of the cervix:* The symptoms are hemorrhage (which gradually becomes more constant and profuse), pain, and discharge (this is at first serous and odorless, later becoming bloody, mucopurulent, and of a fetid odor). The diagnosis is made on the physical and microscopical examination. The cervix is hard and nodular, and the mucous membrane seems immovably fixed to the underlying tissue. These nodules break down, the entire cervix becomes ulcerated, or large cauliflower-like masses may fill the upper part of the vagina. The diseased tissue is friable and bleeds upon touch.

The treatment is removal of the uterus, provided the disease is limited to the cervix.

3. *Symptoms of acute intestinal obstruction:* "Sudden severe pain referred to the umbilicus comes on, perhaps, after an effort. Shock, evidenced by a weak pulse, a cold, clammy skin, and a subnormal temperature, accompanies the pain. The pain, intermittent at first, becomes continuous. Vomiting is persistent, and soon becomes fecal smelling. The patient becomes exhausted by the vomiting and inabliity to take food. The abdomen becomes distended, and if the obstruction is not relieved, perforative peritonitis follows, so that the patient dies in about seven to ten days from the onset. Constipation is usually absolute, though the lower bowel may empty itself at first."

Treatment: The only thing that can give the patient the chance he ought to have is immediate operation. It is advisable to wash out the stomach before the operation, so that intestinal contents may not be vomited and inhaled during the operation. Three objects are aimed at: (1) To empty the distended bowel above the obstruction; (2) to relieve the obstruction; (3) to treat the strangulated intestine. In cases that are almost moribund, the abdomen should be opened with cocaine or eucaine anesthesia; a distended coil is pulled out and tapped, a Paul's tube being subsequently tied in. The peritoneal cavity is protected with gauze packing during these manipulations. The bowel is stitched to the abdominal wound after the feces and flatus have drained away. No attempt at relief of the obstruction can be made in these cases till a later date, and, of course, a high death-rate must be expected.

In less severe cases the abdomen should be opened in the midline below the umbilicus, and a systematic search made for the cause of the obstruction. The hernial orifices are first examined, then the cecum. If the cecum is distended, the obstruction lies below it; if collapsed, above it. In the former case the sigmoid should next be examined. If collapsed, the colon must then be traced backwards till the obstruction is found. If the cecum is collapsed, the intestine must be pulled out a foot at a time and examined, beginning with the ileum, and replacing it as each part is done with. If the intestine is much distended, several coils may be tapped and emptied, to facilitate the search."—(*Aids to Surgery.*)

4. *Cellulitis* is diffuse spreading inflammation in the subcutaneous tissues. *Treatment: Local*—Free and early exit to the pus and sloughs must be given. Incisions exposing the whole area are essential, and no pockets should be left. The part should then be dressed with gauze fomentations of 1 in 40 carbolic or 1 in 2000 perchloride. The continuous bath must be used if fomentations do not answer. Injection of antistrep-

tococcic serum, 10 c.c. three times a day, is sometimes useful. *General Treatment* consists of feeding the patient well with milk and eggs and giving plenty of stimulant.—(*Aids to Surgery.*)

5. *Enlarged prostate is characterized by:* Slowness in starting urination; difficult micturition; frequency of micturition, particularly at night; the presence of residual urine, as may be demonstrated by catheterizing the patient just after he has urinated; dull, aching pain in the perineum and above the pubes; enlargement of the lateral lobes of the prostate; there may be cystitis and retention of urine. *Palliative treatment* consists in: Mild and unirritating diet, avoidance of alcohol, taking plenty of milk or water, or other diluent. Alkalies and sedatives should be taken, also urotropin or other antiseptic so as to prevent cystitis. Regular catheterization, at least once a day, preferably in the evening, and with due aseptic precautions. *Operative treatment* is excision of the prostate gland.

6. *Simple goiter:* Fulness in the neck; thyroidal tumor moving with deglutition, the enlargement being either uniform or irregular as the whole thyroid or only a part of it is affected; and evidence of pressure on the trachea, esophagus, sympathetic, or recurrent laryngeal nerve. Sometimes there may be paroxysmal dyspnea, which may prove fatal.

Toxic goiter: The cardinal symptoms are exophthalmos, thyroid, hypertrophy, tachycardia, and muscular tremor. *Tachycardia* and cardiac disturbance appear early and very constantly. The pulse rate varies from 100 to 200 or more per minute. There is anemia, and from this and the rapid, violent action of the heart, dilatation and hypertrophy may follow. Hemic murmurs and murmurs of relative insufficiency are therefore common. Palpitation is frequent and distressing; the carotids pulsate visibly. *Exophthalmos,* or protrusion of the eyeballs, may be but slight, or so marked that the lids cannot be completely closed. It imparts a staring look of fear or horror to the face. It is sometimes unilateral. It may be caused by (1) venous congestion, or dilatation of the retro-bulbar arteries, (2) overgrowth of the orbital fat, (3) contraction of Müller's muscle. It is attended by certain classical signs—(1) Retraction of the upper lid, so that the sclerotic is seen all around the cornea. (2) When the patient looks down, the upper lid follows the movement of the eye slowly and imperfectly, so that a larger area of sclerotic is seen above the cornea. *Von Graefe's sign.* Other ocular phenomena may occur. There may be ptosis; imperfect convergence on near vision; temporary paresis or paralysis of the third, fourth, or sixth nerve, causing strabismus. The fundus is usuallly normal. *Thyroid enlargement* is moderate in degree, the right side being usually the larger. It may occur early or late. The gland is soft and elastic at first, later firmer and nodular. Systolic thrill may be felt over it, and systolic murmur heard. *Tremor* may affect the limbs only, or the whole body. It is most notable on holding out the hands, palms downward, and consists of rapid, fine rhythmic movements of the whole hand, but not the fingers separately. Any one of these symptoms may be absent at a given stage of the disease; of them all, tachycardia is the most constant. Other symptoms that may occur are digestive disturbances—variable appetite, sometimes vomiting, often diarrhea; wasting; polyuria, glycosuria, albuminuria; flushing of the head and face, free sweating, occasional pyrexia; cutaneous eruptions; mental alterations—depression, melancholia, or even mania."—(Wheeler and Jack's *Handbook of Medicine.*)

Treatment of Innocent Goiter. Removal of the patient from goitrous district, iodine and iodides, thyroid extract. This drug treatment only acts in parenchymatous cases in young patients. Marked diminution will occur in one month or not at all. Local applications—iodine and mercuric iodide ointment—may be applied to the goiter, but the effect is very slight. EXTIRPATION.—The operation of choice in diffuse goiter. One half or more of the gland is removed in its capsule. RESECTION is similar to the above, but the gland is cut through, so as to leave behind the part so intimately connected with the recurrent laryngeal nerve between the cricoid cartilage and esophagus. Both lobes may be removed in this manner. ENUCLEATION is the operation for cysts and adenomata, which are shelled out from a capsule formed by thinned gland substance.

Exophthalmic Goiter.—Treatment. PARTIAL THYROIDECTOMY has a mortality of 12 per cent., and in only about 30 per cent. of cases does a cure result. The patients die from shock or from acute thyroidism. ARTERIAL LIGATURE. Both superior and one inferior arteries are tied, and some improvement results. SYMPATHECTOMY. Removal of both cervical sympathetic cords, including the superior ganglia. The mortality is high (12 per cent.), and the results are uncertain. The operation should be performed under local anesthesia. —(From Grove's *Synopsis of Surgery.*)

7. "*Abscess of the liver* is most frequent in the inhabitants of tropical countries and in alcoholics. Infection may be direct, as in wounds or when it extends from neighboring organs; it may travel up the bile ducts, particularly when they are obstructed; and it may be carried by the blood stream, either hepatic, as in general pyemia, or portal, as in abscesses following infective lesions in the area drained by the portal vein, *e.g.* appendicitis, and dysentery, or other forms of intestinal ulceration. Hydatid cysts may suppurate, and in tropical countries a contusion may be followed by an abscess. The organisms most frequently found are streptococci, staphylococci, and the colon bacillus. In that form following amebic dysentery (*tropical abscess*) the pus is frequently sterile, the organisms probably having perished as the result of the chronicity of the case. Ascarides, distoma, and coccidia are possible, but rare causes of hepatic suppuration. Tropical and traumatic abscesses are usually solitary and occupy the right lobe; pyemic abscesses small, multiple, and hence rarely amenable to treatment.

"The *treatment* is *hepatotomy* by the abdominal or thoracic route, depending upon the situation of the abscess. If the former is chosen, the abdomen is opened, usually by a longitudinal incision, below the costal arch. If the liver is adherent to the abdominal wall, the abscess may be opened without danger of contaminating the peritoneal cavity. In the absence of adhesions the peritoneal cavity must be protected by gauze packing. The abscess is located with a hollow needle, and opened by passing a knife or a cautery blade along the needle. The abscess is irrigated, and drained with a rubber tube, the free portion of the cavity being lightly packed with gauze. After removing the gauze which protects the peritoneal cavity, the liver below the opening of the abscess may be sutured to the abdominal wall. When the abscess is high on the dome of the liver, the transpleural or thoracic operation is indicated. The abscess is located with the needle as directed above, the rib below the needle excised, and, if the pleural cavity is obliterated at this point by adhesions, the abscess opened as previously described. If there are no adhesions, the two layers of the pleura should be stitched together with catgut."—(Stewart's *Manual of Surgery.*)

8. *Treatment of fracture of the ribs:* Strips of plaster reaching from the spine to the sternum should be placed over the injured side during deep expiration. The strips should overlap, and a bandage should be put on over the plaster. If the fracture is due to direct violence, no strapping should be used, but the patient kept still by placing sand bags on either side. Ribs always unite readily.

"Fracture of the ribs complicated with visceral injury is highly dangerous, and requires confinement to bed. The treatment is that of the visceral injury. If there be bloody expectoration, apply adhesive strips as above indicated, put the patient to bed reclining on a bed-rest, keep him quiet, subdue the circulation, and employ opium, diaphoretics, and expectorants (a good mixture consists of squill ipecac, ammonium acetate, and chloroform; opium is given separately). Inflammations of the lung or the pleura, fortunately, are apt to be localized, and are treated as are ordinary inflammations of these parts. If signs of pulmonary injury are severe from the start or become worse under medical treatment, incise, resect a rib, arrest hemorrhage, and drain the pleura. In laceration of an intercostal artery incise and try to ligate; if unable to ligate, resect a rib and apply a ligature. If the signs point to internal bleeding, resect a rib, search for the bleeding point, and ligate. Emphysema usually soon disappears; but if it does not, make many small incisions in the cellular

tissue, dress antiseptically, and employ pressure. When there arises a sudden attack of dyspnea, which is prone to happen in these cases, and in which the face becomes blue, the heart labors, and suffocation seems imminent, bleed the patient almost to syncope."—(Da Costa's *Modern Surgery.*)

9. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downward from behind. The lower fragment is driven backward and upward, and rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture.—(*Aids to Surgery.*)

Pott's fracture is very common, and is due to indirect violence, such as turning over on the inside of the foot. The strain tears through the internal lateral ligament of the ankle or tears off the tip of the malleolus; then the astragalus is pressed against the inner side of the external malleolus by the continuation of the violence. The fibula is overbent, and breaks about three inches above the tip of the malleolus. At the same time the foot is displaced outward or outward and backward. In many cases, however, the displacement is slight.—(*Aids to Surgery.*)

10. In *compound fracture of the thigh* the edges of the wound are cleaned, bleeding is stopped, dead tags of flesh or bone are removed, and the fracture reduced. Care must be taken to preserve the normal line of the leg and thigh; the anterior superior spine, the inner edge of the patella and the great toe must be in a straight line. Extension by weight and pulley will be required. The limb is cleansed and shaved, and a broad strip of adhesive strapping is applied to each side, extending from two inches above the knee to an inch or two above the malleoli. "Large pads of wool should be introduced between the malleoli and the sides of the strapping, to prevent the skin over these processes becoming chafed. A cord is fixed to the stirrup and passes over a pulley at the end of the bed, and is there secured to a tin can which is filled with shot up to the required weight. If now the foot of the bed is raised on blocks, extension and counterextension are obtained, the patient's body acting as a counter-extending weight. When the fracture has been manipulated into a good position under an anesthetic (it is always necessary to control the fracture with some splints before the anesthetic is given), the extension apparatus is applied, and Liston's splint is bandaged to the limb. A proper splint of this kind should extend from the axilla to below the foot, and it is secured to the patient in three places: (1) round the thorax, (2) round the limb at seat of fracture, and (3) to the leg and ankle. In securing the thorax it is necessary to take the first turn of the bandage round the splint from within outward and then round the back of the patient's thorax, the direction of the bandage in this way preventing the natural tendency of the splint to rotate forward. Several turns should be taken round the thorax in order to retain it in position. The remaining bandages should be secured from without inward, in order to check the tendency of the foot and leg to roll outward. In order to prevent the rotation of the limb a method devised by Cheyne and Burghard may be adopted. This consists in securing the limb at the level of the popliteal space to a short splint, 8 by 4 inches, by means of a plaster of Paris bandage. The presence of this splint effectually prevents any rotation, either inward or outward. Special care must be taken to see that the malleoli and the skin over the heel are not subjected to any great pressure. If the fracture is put up in this way it must be kept up for six to eight weeks, and the amount of weight applied to the limb must be varied according to the age of the patient and the tendency to deformity. Roughly, half a pound a year will be found to answer most purposes, but if there is much spasm the amount can be increased up to 20 pounds. At the end of six weeks, during which period the limb should have been regularly massaged—this can usually be done without disturbing the extension—the patient should be got up, and some form of retentive apparatus applied. A Thomas' splint is a very valuable form of apparatus, since it enables the patient to get about, and allows of active movements being undertaken, while he himself can hobble about on crutches. If such treatment is not considered advisable, he should be kept in splints for eight weeks, and then allowed to lie in bed without any apparatus on at all, while the limb is regularly massaged, and he should be encouraged to get up for a short time on crutches, gradually exercising the limb, until at the end of about ten weeks he is walking on it as before."—(Pye's *Surgical Handicraft.*) Some surgeons advise immediate operation, and cut down on to the fractured bone and, after reduction, fix the fragments by two or three Lane's plates. If gangrene results from injury to the popliteal vessels, amputation may be necessary.

11. *Treatment of shock:* Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermically, may be necessary for the relief of pain. Adrenalin solution is administered into the arterial system.

In surgical operations *shock may be largely prevented* by reassuring nervous patients, keeping the patient warm, the avoidance of the excessive catharsis, and semi-starvation that often prevail before operations, the administration of strychnine and atropine before operation, the avoidance of delay and undue exposure handling of parts during the operation, prompt checking of hemorrhage, and by using the utmost gentleness. With a view to preventing the passage of exciting afferent impulses, Crile advocates "blocking" of the nerves by the injection of a 1 per cent. solution of eucaine into their substance on the proximal side of the field of operation.

12. *Sepsis* is a general term which indicates that an operation wound or an accidental wound has become infected with bacteria. These may be either putrefactive or pyogenic organisms.

The putrefactive organisms can only grow in dead tissues, but the toxins formed by them are so irritating as to be able to cause sloughing of the surrounding parts, as in phagedena. If absorbed, a high temperature is produced, as when a portion of putrefying placenta is retained in the uterus.

The pyogenic organisms can grow in living tissues, and also produce toxins. The organisms may invade the tissues in the neighborhood and give rise to erysipelas or cellulitis, or get into the circulation and cause pyemia of septicemia. Hectic fever, septic fever, and sapremia, are terms used according to the amount of absorption of toxin, but the process is the same in all. Once a barrier of granulation tissue is formed by the reaction of the tissues, and so long as the septic material is not retained under pressure, the fever subsides. The symptoms are proportionate to the dose absorbed.

Treatment.—Remove the putrefying mass or open the abscess and provide free drainage. Administer stimulants and plenty of food. If the patient be very bad, intravenous injection of 2 pints of saline solution repeatedly, produces diuresis and diarrhea, and helps to eliminate the toxins. Purgatives also have the same effect."—(*Aids to Surgery.*)

SPECIAL MEDICINE.

1. "*Mechanism of Accommodation*—The lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle (especially the circular fibers) contracts, drawing forward the choroid and relaxing the suspensory ligament; this diminishes the tension of the lens capsule and allows the inherent elasticity of the lens to increase its convexity. The change in curvature affects chiefly the anterior surface of the lens. This is Helmholtz's theory and the one usually accepted. Lately

Tscherning has advanced a different theory; he maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction and that this causes peripheral flattening of the lens with bulging anteriorly at its center. The act of accommodation is accompanied by contraction of the pupil, and (in binocular vision) by convergence of the visual lines." —(May's *Diseases of the Eye.*)

2. IRIDOCYCLITIS. *Causes:* — Syphilis, traumatism, rheumatism, eyestrain. *Symptoms:*—The most characteristic symptom is the deposit of exudate on the posterior surface of the cornea; it is distributed in isolated dots arranged in a triangle, with its base at the lower margin of the cornea, and its apex upward; opacity may ensue; the pupil may be sluggish, and the tension slightly increased. *Diagnosis:*—This is made by the addition of the spots of exudate on the posterior surface of the cornea and the tenderness of the ciliary region to the symptoms of iritis.

3. BLEPHARITIS MARGINALIS SQUAMOSA. *Causes.*—Uncorrected ametropia; some inflammatory process, such as conjunctivitis, keratitis, etc.; inflammation of the roots of the cilia; or the condition may be the result of strumous diathesis. Lice are sometimes a cause. There is also reason to attribute it to special bacteria. Dirty children are very susceptible to blepharitis. Continued eyestrain undoubtedly lies at the bottom of many obstinate cases. Obstruction of the lacrimal apparatus is a cause not to be overlooked.

Symptoms.—The lid-edges are swollen and reddish, and may cause intolerable itching and soreness. There is a gummy and yellowish secretion in the lashes and on the skin near the lid-edge, which, when dried, deposits as scabs and crusts. The lids are glued together after being closed for some time, particularly in the morning. The eyes tire easily. Eczema may be present about the lid-edge, and possibly in other parts of the body. The cilia are often dwarfed or entirely absent, causing a disagreeable disfigurement.

Treatment.—These cases are sometimes very obstinate, and despite all efforts at relief they cause the patient long years of discomfort, and produce a most annoying facial blemish. First of all, search for one of the causes enumerated. It is advisable to examine the refraction of the affected eyes, and be sure that the lacrimal apparatus is unaffected. Treat any possible cause. All the scales should be removed and the lid-edges kept clean and fresh. For this purpose warm water or a weak boric or bichloride solution (1:5000) should be used. In the eczematous variety bichloride in itself is an efficient remedial agent. The local treatment by massage, with a weak Pagenstecher ointment, is probably the best at our command.—(Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

4. ACUTE SUPPURATIVE OTITIS MEDIA. The signs and symptoms are: Pain (lessened when drum perforates), fever (100° to 104° F.), tinnitus, deafness (usually partial only), and purulent discharge (after perforation). *Treatment:* Dry heat allays the pain. Warmed water or warmed carbolic acid solution (1:40) may be used. Inflations, aspirations, etc., should be avoided. If the nares are filled with tough secretions, a spray of Dobell's solution may be used. If the pain continues over six hours in a child or over twelve hours in an adult without spontaneous perforation of the tympanic membrane, paracentesis of that structure should be performed. The concha and meatus should be smeared with petrolatum to avoid chapping, and the secretions should be gently mopped off as they appear.—(*Pocket Cyclopedia.*)

5. *Removal of aural polypi.*—"Whenever a polypus is large, and particularly if it have a pedicle, the best method of removing the same is by means of Blake's snare. . . . Before attempting to snare a polypus, the canal should be carefully syringed with a bichloride solution, 1:3000, to remove all secretion, and then carefully dried. Cocaine solution, 10 per cent., should then be instilled warm into the ear, and after a few moments the surgeon should make out with the probe the point of attachment of the polypus. It requires considerable practice and skill to apply the loop of wire about the growth. The removal of the latter may be followed by considerable hemorrhage, which can be controlled by tamponing the canal with styptic cotton."—(Bacon's *Manual of Otology.*)

6. *Tinnitus aurium* is the name given to any subjective sounds heard in the ear. The chief causes are: neurasthenia, impacted cerumen, otitis, and other ear diseases; Ménière's disease, obstruction of the Eustachian tube, anemia, leukemia, cerebral hyperemia and anemia, arteriosclerosis, gout, digestive disorders, excessive use of alcohol or tobacco, and the use of certain drugs such as quinine or salicylic acid.

7. *Acute catarrhal inflammation of the antrum of Highmore. Symptomatology.*—There is usually a history of acute rhinitis and pain in the region of the antrum, extending into the nose and angle of the jaw. There may be headache and some tenderness upon pressure in the canine fossa. The cheek of the affected side is frequently swollen. The discharge from this nasal cavity sometimes produces smarting and burning about the meatus of the nose. If the affection is due to diseased teeth, there may be pain and redness in the region of the tooth. With the enumeration of the above symptoms the diagnosis is usually simple. There is seldom any shadow to be detected upon transillumination. The nasal cavity of the affected side is observed to be congested. The middle turbinated body is swollen and impinges upon the lateral wall. There is usually little or no discharge to be detected coming from the region of the ostium.

Treatment.—The general treatment is directed to the restoration of the general metabolism. The patient should avoid exposure to cold and damp weather and be warned against the general conditions predisposing to acute catarrhal inflammation. The bowels should be flushed with a saline and the patient given salicylate or benzoate of soda or aspirin in ten grain doses, three times daily. The local treatment by the physician consists in applying a five per cent solution of cocaine and 1/5,000 adrenalin solution to the middle meatus. Following this, the nasal cavity should be thoroughly cleansed by spraying with a mild alkaline, antiseptic solution. A fifty per cent. solution of argyrol should be applied to the region of the ostium with a cotton-tipped probe. The nose is then sprayed with a two per cent. solution of camphor and menthol in albolene. The patient should be instructed to cleanse the nose with a Dobell's or Seiler's solution, three times daily, before meals. Hot applications in the form of a hot-water bag should be applied to the region of the antrum for one-half hour, morning, noon, and night.—(From Kyle's *Manual of Diseases of the Ear, Nose and Throat.*)

8. *The nasal turbinates should be removed,* in some cases of hypertrophic rhinitis, cystic conditions or polypi when they cause nasal obstruction.

9. *Epistasis,* "or bleeding from the nose, has a variety of causes. Traumatism, ulceration, tumors, and foreign bodies, are local causes. A small abrasion on the anterior part of the septum is commonly found. General causes are increased arterial tension, as in chronic nephritis; blood changes, as in hæmophilia, purpura, and scurvy; mitral obstruction."

Treatment:—"A local cause should always be looked for, and if a bleeding-point be found, it can be stopped with the galvano-cautery or a solution of chromic acid on a swab. Cold applied to the root of the nose stops many cases. Occasionally the injection of adrenalin hydrochloride solution will stop the bleeding. If these measures fail, the nose must be plugged with gauze after placing a pad over the posterior nares. For this purpose Bellocq's sound is often used to get the piece of silk which holds the plug into place."—(*Aids to Surgery.*)

10. In *diphtheria* the onset is more gradual; the temperature rises to about 102° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick, grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon re-forms and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white, cheesy spots or plugs, which consist of broken-down epithelium and are easily brushed away; Klebs-Loeffler bacilli are never found.

11. CHRONIC PHARYNGITIS:—"Chronic inflammation of the pharynx follows repeated acute attacks, prolonged irritation, long-continued overuse and improper use of the voice, chronic rhinitis, and digestive disturbances. It is common in hucksters, public speakers, singers, and smokers. It is more common in adults than in children; and the inhalation of dust and irritating gases may also induce the trouble. In the early stage the mucous membrane is in a state of chronic hyperemia; and is thick, swollen, and studded with distended follicles and enlarged lymphatic glandules which give to it a granular appearance. In the later stage the mucous membrane undergoes atrophic changes, and is anemic, glossy, and dry. As a result of these changes the voice is husky, and the throat is dry. Distress follows the use of the voice and there is a constant desire to clear the throat."

Treatment:—"The underlying causes should be promptly removed. Tonics such as iron, quinine, strychnine, and cod-liver oil, together with plenty of fresh air, should be prescribed. Locally, Dobell's solution and similar antiseptic solutions should be used in the pharynx and nose. When the granules are present, astringent applications, such as zinc sulphate (gr. v to f ʒi) and silver nitrate (gr. x to xx to f ʒi), or the galvanocautery may be employed. A spray, consisting of menthol (gr. ii), eucalyptol (gr. i), and liquid vaseline will be productive of great relief. The condition may prove very resistant to treatment."—(Hughes' *Practice of Medicine.*)

12. VINCENT'S ANGINA:—"This is a form of sore throat due to two organisms, the fusiform bacillus and the spirocheta darticola. It occurs chiefly in children and young adults; the eruption of the wisdom teeth is said to be a predisposing factor. Bad hygiene, and the use of alcohol and tobacco are favoring conditions.

Symptoms:—Two forms are recognized: (1) The ulceromembranous variety, which is the most common and in which both the bacillus and spirochete are found. In this form there are malaise, sore throat, headache, fever, dysphagia, and fetid breath; later ulceration of one or both tonsils occurs. (2) The diphtheroid variety, which occurs in about 2 per cent. of cases only. This form is due to the fusiform bacillus alone, and is characterized by a distinct false membrane on an inflamed base. Otherwise the symptoms are the same as those found in the ulceromembranous variety. A smear and culture will decide whether the case is one of diphtheria or not.

Treatment:—An antiseptic mouth wash, and the application of tincture of iodine twice a day are indicated. The disease is not amenable to antitoxin. On account of the presence of a spirillum, salvarsan has been tried, and (it is claimed) with satisfactory results."—(Hughes' *Practice of Medicine.*)

Miscellany.

Summary of the Morbidity from Contagious Diseases in France During the War.—Bonnette sums up this subject in *La Presse Médicale* for July 14, 1920, xxviii, 48. The simple eruptive fevers were neither more numerous nor more fatal than normally, and this means that their pulmonary complications were as usual and no more. Diphtheria was fought throughout the war period. During the five-year period there occurred in the army of the interior 15,271 cases with 378 deaths, and in the civilian zone occupied by the army 11,433 cases with 228 deaths, the percentages being respectively 2.4 and 2. Healthy carriers were treated with dried serum, otherwise known as Martin's pastilles, which was insufflated into the rhinopharynx. Cerebrospinal meningitis was quite prevalent, but not more contagious than usual in peace; disinfection of the rhinopharynx was effected with Vincent's solution —a mixture of idodine and guaiacol. Dysentery was common in the estivoautumnal season and was combated effectually with Dopter's serum and emetine.

Vincent's campaign against typhoid fever was so successful that it was credited with the victory of the armies. The results of antityphoid vaccination has been sufficiently quoted elsewhere. In regard to smallpox but 20 cases occurred during the entire war (as contrasted with 10,000 in the Franco-Prussian war), thanks to Jennerian vaccination. As for malaria it had no incidence in France worthy of mention; on the Macedonian front, however, it stole a march on the sanitary forces, but Sergent and Visbecq were thoroughly successful finally in their somewhat belated crusade against the anopheles. Spotted typhus hardly crossed the frontier, although France was almost surrounded by it. This result was attained only through a most strenuous campaign by the Marine as well as by the ordinary sanitary services. To sum up, everything was well in hand except the influenza, the course of which showed it to be quite inevitable in all countries.

The Disease and Death of General Gallieni.—A brochure has just been issued on this subject by Dr. Laval which is reviewed by the *Bulletin Médical* of July 10, 1920, xxxiv, 35. The deceased is admitted to have been one of the great figures of the late war, he having acquired the sobriquet of the "savior of Paris." In passing it may be remarked that he will soon be honored by a statue of bronze cast from Teutonic guns. The death of the General called forth a whole body of reports comprising more or less of legend and myth, which recalls the death of Skobeleff many years ago. Despite improbability and want of evidence the watchword became "cherchez la femme." It was "certain" that the deceased had a strong penchant for a well-known lady. There had been an assignation in the studio of a prominent sculptor, etc. He had undergone an operation because of approaching marriage. He had committed suicide with a revolver. He was a sufferer from cancer of the prostate, a disease which is hardly conducive to matrimony. He had even succumbed to an operation for this disease and the anesthetic was accused as well as the poor judgment of the surgeons. The author is able to dispel this cloud of rumors. In April, 1919, he was consulted by Gallieni and found an hypertrophy of the prostate, so that the basis of the rumor is apparent. Death occurred a little over two years later and was, to say the least, premature. It was thought best to delay the book until the present time. When Laval saw the General in December, 1915, he was struck by the great change in his appearance. He looked cachectic, which he himself attributed to the hardships and responsibilities of war—for example, he had hardly slept for three months. Prostatectomy in two stages was performed in the following spring with an interval of twenty-eight days. Dr. Marion, the genitourinary surgeon, was in charge. Laval gave the anesthetic. Death occurred three days after the second stage, of hemorrhage, while making the first change of dressings. Dr. Marion gave his own blood for transfusion. Madame Gallieni died a few hours after the declaration of war in 1914.

Goat's Milk.—According to the annual report of the California Development Board, the only goat milk condensery in the world is located at Pescadero, San Mateo County, Cal., where a herd of 6,000 milk goats is maintained by the Widemann Goat Milk Laboratories. The demand for canned milk for tuberculous patients is said to far exceed the supply, goat milk having been found a particularly valuable nutrient for consumptives. The number of milk goats in California has increased 50 per cent. in the last two years. A large farm at Cool, Eldorado County, was recently stocked, and the production is to be used exclusively in the manufacture of goat milk cheese. That goat's milk is exceptionally rich in vitamines undoubtedly accounts for its growing popularity for food purposes, especially when high nutritive value is desired.—*American Medicine.*

Laboratory Activities in South America.—The *Revista Sud-Americana de Endocrinologia, Immunologia y Quimioteraphia* is now in the third year of its existence. It is published in Buenos Aires in monthly issues and covers all national as well as foreign activities in endocrinology, immunology, bacteriology and parasitology, serodiagnosis, sero therapeutics, and chemiotherapy. In addition to human and animal pathology the periodical has departments for vegetable pathology and industrial chemistry. The personnel comprises a scientific director, Dessy, who is also in charge of the laboratories of the Italian Hospital and who directs the departments of pathological anatomy and bacteriology; Professor Krogh, who is director of the department of serums and vaccines; Professor Spegazzini, an agricultural engineer, who directs the department of vegetable biology, and Engineer Sourbeck, director of industrial chemistry.

The institution appears to represent a centralization of the analytical activities of the metropolis. Another publication of the same scope, the *Archivos de Biologia,* is a monthly review of the activities of the Paulistic Laboratory of Biology, published at Sao Paulo, Brazil, and in its fourth year. This institution prepares sera, vaccines, internal secretions, ferments, and pharmaceutic products such as intravenous solutions, etc.

HOW "TUBERCULOSIS SCHEMES" FAIL, AND WHY.*

BY STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

CHAIRMAN OF THE STATE TUBERCULOSIS COMMISSION OF CONNECTICUT.

BY "tuberculosis schemes" I mean—and I suppose the designers of your programme meant—only such attempts at prevention or treatment as have been sanctioned or adopted by a considerable number of the serious leaders of civilization's anti-tuberculosis campaign.

One who surveys "tuberculosis schemes" from the cooler altitudes of the office of a board of health, or of a registrar of vital statistics, can contend with force and figures and some truth that "tuberculosis schemes" have not failed.

"Certainly," he can argue, "the death-rate from tuberculosis is only about half as high as it was forty years ago. All 'tuberculosis schemes' deserving of consideration are less than forty years old. The 'tuberculosis schemes' of living in the open, of sleeping in rooms with open windows, of sending consumptives to sanatoria, of establishing tuberculosis dispensaries, of condemning tuberculous cattle, of teaching the contagiousness of tuberculosis, of providing occupational therapy for sanatorium patients, of establishing farm colonies or villages for the graduates of sanatoria, of conducting tuberculosis surveys, of penalizing the filthy habit of expectorating in streets and trains and other public places, none of these tuberculosis schemes has failed. All have succeeded. It is true that they have not banished tuberculosis from the earth, but they have succeeded in keeping millions of human beings free of active tuberculosis who otherwise would have died of tuberculosis. And as the preventing of deaths from tuberculosis was the sole object of all these 'tuberculosis schemes,' how have these 'tuberculosis schemes' failed?"

I would answer that question in this way: All these "tuberculosis schemes" have failed because (1) even in the countries where all or some of these "tuberculosis schemes" have been in operation for twenty years or more, every tenth or twelfth funeral is still caused by tuberculosis; and because (2) in spite of the functioning of any or all of these "tuberculosis schemes," tuberculosis continues to drag its victims from the ranks of the rich and the educated as well as from the ranks of the poor and the ignorant; and because (3), while we must admit that these "tuberculous schemes" have reduced the tuberculosis death-rate, there is very little proof that they have reduced the tuberculosis death-rate any more than they have reduced the general death-rate. In other words, "tuberculosis schemes" have simply caused the people to focus their attention on the need of cleanliness—clean air, clean homes, clean food, clean drink, clean streets, clean hands, clean mouths, clean bodies, clean barns, clean cattle, and perhaps clean lives. The "tuberculosis schemes" of the past twenty years have furnished most of the foundation on which rests the present remarkable democratic endorsement of board of health activities. In that way and to that degree "tuberculosis schemes" have been a success, but as they have had no more success in preventing or curing tuberculosis than they have had in preventing or curing scarlet fever, and less success than they have had in preventing and curing typhoid fever, they have been failures. As measures for promoting the general health of the community they have been worth while, but as "tuberculosis schemes" they have been failures and unworthy of the name they bear.

Why Tuberculosis Schemes Fail.—When the doctors and the other superior persons of the beginning of the next century look back smilingly at the history of our frantic efforts to stamp out human tuberculosis, what will they say was the matter with our "tuberculosis schemes"? They will say:

"Oh yes, they were a very enthusiastic lot, those doctors and officials of the first quarter of the twentieth century, but their very enthusiasm was their undoing. They knew thoroughly the tragedies and the desolation wrought throughout the earth by tuberculosis. They knew that in all cases of tuberculosis the tubercle bacillus was found. They knew that by injecting tubercle bacilli into animals they could cause tuberculosis in the injected animals. They, therefore, concluded that tuberculosis was an ordinary contagious disease, and that in order to prevent tuberculosis all that was necessary was to get rid of all the tubercle bacilli on earth. With this object in view the tuberculosis authorities of the civilized countries of the world began a campaign for discovering and publishing and segregating all tuberculous men and animals. It was not until after many years, and after the expenditures of enormous amounts of energy and vast sums of money, and after the erection of a tremendous machine for purposes of propaganda, that it began to be realized that these results were impossible of accomplishment.

"Then it was taught that during childhood practically all civilized human beings became infected with tuberculosis, and that this childhood infection,

*An address delivered October 8, 1920, in St. George's Hall, Liverpool, England, at the Eighth Annual Conference of the British National Association for the Prevention of Tuberculosis.

though it frequently flamed out into clinical tuberculosis in adult life, had usually the effect of rendering human adults immune to any new infection of tuberculosis. This teaching led of course to the abandonment of all tuberculosis schemes that had for their object the prevention of the tuberculous infection of adults, and led to the intensifying and enlarging of all tuberculosis schemes that had for their object the safeguarding of children from tuberculous infection.

"The new strategy had the immediate effect of reducing considerably the general morbidity of children, and slightly the tuberculosis morbidity of children, but still throughout the civilized world one funeral in every ten or twelve funerals continued to be from tuberculosis.

"Despairing of solving the problem according to any accepted formula, many of the leaders of the anti-tuberculosis forces began about the middle of the last century to look for a new formula. At first cautiously, they permitted themselves to listen to certain uninfluential medical radicals, who for years had been asserting (1) that the tubercle bacillus was only one phase of a bacterial cycle; and (2) that if all the tubercle bacilli and all the tuberculous animals, human and brute, were killed to-day, there would be new tubercle bacilli and newly tuberculous animals in every civilized land before another twelvemonth had rolled around; and (3) that in order to prevent tuberculosis it was necessary simply to prevent the appearance of the tubercle-bacillus phase of the bacterial cycle; and (4) that in order to cure tuberculosis it was not necessary to kill the highly resistant tubercle bacilli, but it was necessary to cause tubercle bacilli to pass as bacilli into the next phase of their bacterial cycles, a less resistant, non-acid-fast phase in which they were easily dissolved by the cells and secretions of the infected animal. The simplicity of this new formula aroused a smiling incredulity almost everywhere, but some of the less sceptical took up the matter seriously and instituted elaborate research along the lines suggested by the new formula.

"The trouble with the tuberculosis campaign up to that time, or in other words, the reasons of the failure up to that time of all tuberculosis schemes, were—

"A. The over-emphasis given to the value of the activities of the non-medical anti-tuberculosis workers.

"B. The disinclination of most physicians to join heartily in a medical campaign dominated by non-medical functionaries.

"C. The disinclination or inability of these non-medical officials to endorse or utilized medical research.

"D. The obtuseness of even the medical officers of the tuberculosis campaigns to the importance of the following facts:

"(1) Aside from its specific toxic power, the most important character of the tubercle bacillus is its waxy, resistant capsule.

"(2) Serological tests prove that there is a family relationship between the tubercle bacilli and all bacilli that possess these waxy capsules.

"(3) Many ordinary non-acid-fast bacteria, when subjected to an unfavorable environment, develop waxy capsules, and thus become demonstrably family relations of the tubercle bacillus. This was known to be true of colon, *subtilis*, *typhosus*, *mycoides* and streptothrix.

"In this twenty-first century it is easy to see the importance of these things, but it is probable that even now the world would not have been convinced if the results of the great experiment carried out in the year 2031 and '32, simultaneously by Great Britain, France and the United States, had not been so conclusive. This experiment consisted in subjecting one-half of a herd of 100 proven non-tuberculous cows, for a period of two years, to a rigidly controlled insanitary environment such as obtained everywhere at that time in most dairy farms. The cows were kept knee-deep in their own manure in new but unlighted or badly lighted, and unventilated or badly ventilated, barns. The fifty control cows were, of course, properly housed, pastured and groomed. In all thee countries the results were the same. The tested animals became tuberculous, and the controls remained free of tuberculosis.

"Of course there could be no blinking of the great light that shone from this experiment. Soon the public and private laboratories of the world were busy making vaccines, not against the tubercle bacillus, but against the precursors of the tubercle bacillus; and sera, not in the expectation of killing the tubercle bacilli *in sitû*, but in the expectation of forcing the tubercle bacilli *in sitû* to vegetate without their waxy capsules and thus to become easy victims of phagocytosis. The tuberculosis officials, realizing that nothing more could be accomplished by tuberculosis schemes that merely made for general cleanliness, devised in addition measures that had for their object the securing of such special conditions of person and domicile as prevented the transformation of the digestible or innocent, thin-skinned forms of bacterial life into the hard-shelled, disease-producing tubercle bacilli.

"After the forging of these new weapons for the prevention and cure of tuberculosis, the white plague, as it was called, was soon conquered. This was a victory not only of supreme intrinsic importance, but it was a victory that led to many others because of the insight it gave of the causes and source of disease in general; by showing that the death-dealing strains of tubercle bacillus were derived originally from harmless bacterial forms, it drew attention to the theory that all disease-producing germs are simply abnormal developments from forms of bacterial life that under ordinary and favorable conditions of environment are harmless or beneficial to human and other animals. And, of course, it made it clear to all, particularly to the medical historians, that all 'the practical difficulties in connection with the carrying out of tuberculosis schemes' in the first decades of the twentieth century were due to the false hypothesis on which they were all based, namely, that all tubercle bacilli must of necessity have been born of other tubercle bacilli."

APPENDIX.

As a visible argument in favor of my contentions, I have brought from my laboratory in America a few cultures that may interest you. I will not take time to give their detailed life histories, but I will be glad to answer now, or later, questions concerning them.

Avian B.—A strain of Avian tubercle bacilli, that ten years ago grew entirely acid-fast and only at blood temperature, now grows at room temperature and almost entirely non-acid-fast.

Bovine B.—A strain of Bovine tubercle bacilli, that ten years ago grew only at blood temperature, and as pure small acid-fast rods, now swollen into granular and streptothricial rods and coccoids. In very recent years it grows only at room temperature.

Red KI—The first culture of tubercle bacilli ever seen in America was the one sent to Trudeau by Koch nearly forty years ago. This strain, known as KI at Saranac, was, at its best, only mildly pathogenic. Here it is with chromogenic power and growing at room temperature, and non-pathogenic, and, except in milk, almost non-acid fast.

R. R. H.—A strain of ordinary pathogenic human tubercle bacilli, sent to me from England by Dr. Nathan Raw, grown for long periods on glycerine-broth potato. Its first modification was its development of chromogenesis, the second its gradual loss of acid resistance, and the third its acquiring the power to grow at room temperature. In its present condition this strain is ten years old. It does not now cause tuberculosis. On some media it loses almost entirely its bacillary form and becomes coccoid.

512.—Acid-fast bacilli, derived from spores of *Bacillus subtilis*. These spores, made acid-fast by age and lowered temperature, were subjected to the slightly stimulating but difficult environment of normal salt solution and a temperature of 37.4°, and were thus coaxed to vegetate abnormally as very short acid-fast rods. They do not cause tuberculosis. Intraperitoneal injections in guinea-pigs give rise, in ten days, to small nodules that are not fatal, and that disappear in three weeks.

212 ORANGE STREET.

THE EPIDEMIC OF LETHARGIC ENCEPHALITIS.

BY ISADOR ABRAHAMSON, M.D.,

NEW YORK.

ASSOCIATE ATTENDING NEUROLOGIST, MOUNT SINAI HOSPITAL; ATTENDING NEUROLOGIST MONTEFIORE HOME.

IN the winter of 1916-17 there occurred in Vienna an epidemic disease which von Economo named lethargic encephalitis. According to the descriptions given by him and later by von Wiesner, this disease usually began with fever and headache; somnolence followed, which was succeeded by delirium, or which deepened into coma that changed sometimes to death, sometimes to a mild confusion. The afflicted as a rule showed signs of cranial nerve palsies.

News of this strange plague had scarcely escaped from the beleaguered Central Empires when the disease itself suddenly appeared in the outer world. An epidemic, which was described by J. H. Mathewson and Oliver Latham, began in February, 1917, in the Province of New South Wales, Australia; whence it spread to Queensland and to Victoria. It persisted till the following May. The Australian observers described the disease as characterized by fever, rash, sweating, nasal catarrh, headache, somnolence, convulsions, and coma, together with signs of implication of the brain coverings and of the cranial motor nerves. France was next attacked. Netter, Claude, Chauffard, and others studied and described the epidemic there. On February 11, 1918, the first recognized case occurred in England, and an outbreak followed which, with remissions, lasted until January, 1919. Then the disease appeared in Ireland. In 1918 the epidemic was reported as raging also in Uruguay and in Algeria, in Germany and in Greece (September and October).

So far as is known the first recognized case of this epidemic disease in America entered Mount Sinai Hospital, New York City, in September, 1918. October 23, 1918, Major Pothier detected a case at Camp Lee. October 27, a third was discovered by Dr. Ely at Des Moines. Some weeks later Dr. Bassoe in Chicago recognized the fourth case. And their number thereafter quickly multiplied. By January, 1919, the disease had appeared at far apart points all over the United States; but New York City, the initial site of the invasion, remained the point of its maximum concentration. The number of reported cases increased until March, 1919, and thereafter decreased, the epidemic practically disappearing toward June, 1919. In the following September fresh cases began again to come to hospital clinics and their number steadily grew.

Published accounts leave no room for doubt that the epidemic which appeared in Europe was similar to that which broke out in Australia, and later invaded America. Just as the epidemic leaped from continent to continent, and from country to country, so, in the same country, it hopped from place to place. The locality in which the epidemic first appeared tended to remain the area of its greatest intensity. The epidemic invasion of any one area tended to be relatively brief, seldom exceeding three months; but it commonly recurred after a quiescent period of about the same length as the duration of the original invasion. And it affected those of both sexes and of every station. In this epidemic, wherever it occurred on the earth's surface, people were attacked by a febrile catarrh, lethargy, somnolence, or stupor, cranial nerve palsies, and great feebleness. Of these symptoms, that which usually focused the attention of the patient's friends and physician was somnolence. Hence the disease became popularly known as sleeping sickness.

Epidemics of sleeping sickness punctuate the history of medicine. Since the discovery of printing, drowsiness and fever are repeatedly recorded in the epidemics of sweating fevers that have scourged Europe, and that have been studied and described by Jean de Troyes, Ambrose Paré, Ballonius, Willis, Sydenham, Camerarius, Gruner, Hecker, Sennert, Creighton, Hamer, Crookshank, and others. The sweating sickness, *pestis Britannica*, of 1529, was characterized by *somnolentia inevitabilisque sopor*. The Belgian influenzas of 1557-58 produced slumberous patients with half closed eyes. In 1580 both Saxony and Rome were attacked by an epidemic of fever and lethargy, and in 1597 a similar affliction overtook all Germany and Italy. In 1657 an epidemic of febrile lethargy occurred at Copenhagen. From 1672 until 1675 the comatose fever of Sydenham raged in England and in Europe. During 1691 it recurred throughout Germany. In 1712 there broke out in Tuebingen an epidemic of sleeping sickness in which the afflicted showed also signs of morbid changes in the structure of the brain.

Camerarius' description of the Tuebingen epidemic was followed in 1729 by Becaria's account of a plague which attacked Bologna, and in which fever and sleep were the characteristic symptoms. Ozanam relates that in 1745 a considerable outbreak of a catarrhal fever with *soporosité* occurred in Germany. In 1768 an epidemic of fever followed by *coma somnolentium* afflicted France, and was described by Lepecq de la Clôture. In Ozanam's work there is also mention of an epidemic which occurred at Lyons in 1800; and of another, at Milan, in 1802, similar to the 1745 epidemic in Germany.

The accounts of the epidemics which raged before the last century are usually too meager to permit us to determine with certainty the precise nature of the plague. Since these days clinical observation has greatly improved. Recurrent symptom groups have been identified, segregated, and dignified as disease entities. Thus, from the sweating sickness or influenzas, Heine (1840) and Medin (1887) separated the disease which is variously known as poliomyelitis, infantile paralysis, and Heine-Medin's disease. Thereafter, old-time epidemics of socalled influenza were suspected to have had at least a dual nature. And when later (1875) cerebrospinal meningitis was also separated from the influenzas and from poliomyelitis, clinicians realized that what we loosely term influenza is a group of infectious fevers mistakenly confounded with the fever caused by the bacillus of Pfeiffer.

Throughout the war one or more of these obscure fevers laid waste the world. We called it epidemic Spanish influenza. It had come to be of the essence of conservative epidemiology to attribute to the same disease all illnesses in the course of an epidemic, of which the clinical types were within the established scale of variation of the prevailing epidemic disease. This clinical convention, together with the ignorance and isolation in which we were maintained during the war, caused me to communicate the first observations of lethargic encephalitis in America to the New York Neurological Society on January 7, 1919, as observations on the lethargic encephalitis syndrome in the epidemic of Spanish influenza. Subsequently, when I observed that concurrently with the decline of the influenza epidemic, and with the absence of any increase of the other syndromes which the socalled Spanish influenza produced, the number of cases of lethargic encephalitis steadily grew, to an extent that suggested that we were in the midst of another epidemic distinct and different from the Spanish influenza plague, I brought the matter before the February meeting of the society, which thereupon named an investigating committee.

But in thus identifying lethargic encephalitis as a new clinical entity capable of epidemic occurrence, merely the existence of a newly recognized syndrome and not necessarily of a new disease was established. The syndrome of lethargic encephalitis is a physiological manifestation of certain morbid changes in the normal anatomical structure of the human body. Pathologists studied these changes and made inferences from them concerning the individuality of the lethargic encephalitis lesions. Breinl of Australia, by inoculation of disease matter from fatal cases of lethargic encephalitis, reproduced in two monkeys a malady which he described as identical with poliomyelitis. Some competent and careful observers, basing their judgment on facts which will later be mentioned, stressed the dissimilarity between the lesions of poliomyelitis and those of lethargic encephalitis. Others emphasized the resemblance, still others the difference, between the morbid anatomy of so-called Spanish influenza and lethargic encephalitis. And Bassoe, in his admirable article on the pathology of this condition, noted the similarity of the lesions he studied to the lesions reported by Spielmayer and Mott in the sleeping sickness of trypanosomiasis. Mott, however, had had opportunities to study the lesions of lethargic encephalitis before Bassoe, and Mott did not mention any relationship between the two conditions.

In judging the inferences of various pathologists, due weight must be given to their established reliability. Other things being equal, demonstrated similarities with the lesions of recognized and accepted diseases, although valuable, are of less importance than demonstrated differences. Not the similarities but the differences determine the existence of a new disease. Similarity of lesions is not proof of the identity of the agents causing the lesions. Analogous lesions may be produced by very different exciting agents. But differences in the nature of the lesions, not due to differences in the severity, site, extent, or duration of the infection, imply differences in the agents producing the lesions.

Bacteriologists have sought the exciting cause of lethargic encephalitis. Von Wiesner, by intracerebral and intraperitoneal inoculations of brain extract from fatal cases, communicated the disease to monkeys. McIntosh in England, various French observers, and in this country Ayer and Wegeforth, unsuccessfully attempted to repeat von Wiesner's experiment. Failure to transmit a disease by inoculation may arise from many causes. The experimental technique may be faulty. The inoculated virus may have depreciated in virulence below the threshold of pathogenesis. The experimental animal or group of animals may be immune to the infection, or may possess a resistance greater than can successfully be overcome by the injected virus and antecedent or concomitant infections may be needful to sensitize the inoculated animal. Such factors as these cause failure to be referred rather to experimental faults than to inherent impossibility of achievement. Hence a multitude of failures are outweighed by a single incontrovertible success. One successful inoculation established the transmissibility of the infection. Von Wiesner's experiments with monkeys placed beyond reasonable doubt the communicability of lethargic encephalitis. And Cleland and Campbell of New South Wales finally settled the matter.

These brilliant Australian observers made over one hundred and thirty experiments, in the course of which the monkey, the sheep, the horse, the calf, and other animals were successfully inoculated. The virus containing matter consisted of a suspension either in glycerin or in normal saline solution, of portions of the brain, spinal cord, pons or medulla, of human or animal victims of the disease. The virulent suspension or solution was injected

within the brain of the experimental animal. In this way the disease was conveyed from three human beings to five monkeys; from monkey to monkey through fourteen generations; from monkey to sheep and horse and calf; from sheep to sheep, and back again from sheep to monkey. As Flexner and others had demonstrated that the virus of poliomyelitis is transmissible to the monkey but not to the sheep, or horse, or calf, Cleland and Campbell inferred that the virus of lethargic encephalitis differs from the virus of poliomyelitis.

Von Wiesner was able to cultivate, both from animal and from human victims, a Gram positive coccus which was found especially in the leptomeninges. With "pure" cultures of this coccus he reproduced the disease in monkeys. McIntosh followed the technique of von Wiesner, but was unable to find the incriminated coccus. Marinesco of Bucharest, working on material obtained from England, frequently found a Gram positive bacillus, and rarely an associated diplococcus. The Marinesco bacillus was discovered in the meninges, in the superficial nuclei of the pons, and in the walls of blood vessels within inflammatory areas. McIntosh successfully cultivated this bacillus and found it to be an anaerobe for mice. He reported that this short thick bacillus of Marinesco has nothing in common with the bacillus of botulism: and that, in the inflammatory areas, karyokinetic changes gave rise to cell chromosomes so distinct as readily to be mistaken for diplococci. Welsh found no organisms in the portion of the brain and upper cervical cord examined by him for Mathewson and Latham. Wegeforth and Ayer also sought for causal organisms in vain. At Mount Sinai Hospital the search for the exciting agent was fruitless until one day I noticed in a certain case a peculiar green nasal secretion to which I called the attention of the bacteriological staff. A Berkefeld filtrate of a saline solution of this secretion was obtained, which on injection into the brain of a monkey, *Macacus rhesus*, reproduced the disease.

Subsequently, Loewe, Hirshfeld and Strauss, working on the Mount Sinai material, reported that this filtrable virus, obtained from nasal washings and from the mucous membrane of fatal cases, could reproduce the disease both in rabbits and in monkeys. From this filtrate, by the Noguchi method for the cultivation of the *S. pallide*, they obtained cultures of small globular bodies, which appeared bluish or purple when stained with Giemsa solution, or with methylene blue. This filtrable organism they carried to the twelfth generation. They announced that it resembled in morphology, appearance of colonies, and in growth the organism described by Flexner and Noguchi as the exciting agent of poliomyelitis. "It differs in results obtained with animals and particularly in the susceptibility of rabbits to it." (Loewe and Strauss.)

Flexner and Amoss in a series of one hundred and forty experiments were unable to verify the existence of the filtrable organism which Loewe and Strauss had reported or to transmit the disease. There the matter at present rests. The identity and even the existence of a special organism of lethargic encephalitis still remain to be definitely demonstrated. But the characters of the disease indicate it is organismal. And although the actual organism still eludes us, its distinctive and constant pathogenic properties are clearly established. Cleland and Campbell reported that the virus they studied "bred true," reproducing the same disease in one after another of fourteen monkeys. And Loewe and Strauss report that eleven generations of the globular bodies they describe, although cultivated *in vitro*, successfully reproduced the same disease in monkeys and rabbits. This virus of lethargic encephalitis differs from that of poliomyelitis in being transmissible to the sheep, the horse, and the calf (Cleland and Campbell) and in the susceptibility to it of rabbits (Loewe and Strauss). Clinical skill such as was displayed especially by von Economo and von Wiesner; geographical isolation such as occurred in Australia in the epidemic studied by Mathewson and Latham; and the time incidence in America, enabled physicians to recognize the presence in epidemic proportions of a lethargic encephalitis syndrome. Careful examination of the morbid changes which this syndrome expressed showed that these changes resembled but were at the same time distinguishable from the changes produced by poliomyelitis. Bacteriological research demonstrated that the causal virus possessed specific, distinctive and constant characteristics. We are justified, therefore, in concluding that lethargic encephalitis, although related to poliomyelitis and probably also to other protozoon affections, is a separate disease entity, a disease *sui generis*.

It is reasonable to suppose that conditions that predispose a community to epidemic attack should predispose it to attack by all existing microbic agents capable of epidemic attack. It is reasonable to suppose that in lethargic encephalitis we are dealing not with a newly developed epidemic disease syndrome, but only with a newly recognized epidemic syndrome, and further it is reasonable to believe that epidemic manifestations of the lethargic encephalitis syndrome have previously occurred, probably participating in the epidemics of sweating or influenzal sicknesses which historians have recorded, and to invoke a retroactive knowledge to identify cases once diagnosed as botulism, as influenzal meningitis, as poliomyelitis superior acuta, or labeled in some other fashion, now as sporadic cases of lethargic encephalitis, is an inevitable if not very profitable form of speculative activity.

Crookshank has pointed out that it was the custom of the early chroniclers to attribute each epidemic to a general cause, in the search for which they were easily satisfied. The national opprobrium implicit in *Spanish* influenza is detectable in the pestis *Britannica* of 1529. The geographical culprit was followed in the popular mind by the nutritive. The sweating sicknesses were then distinguished as sausage disease, grain disease, radish seed disease, and so forth, according to the prevailing dietetic prejudice of the afflicted people. Then the cause of the epidemic disease became to some extent a matter of interest secondary to the form. The disease entity, the symptom complex, the syndrome, was sought. New diseases were discovered and labeled like other biological specimens. The old accounts of the sweating sicknesses were naturally the domain in which each infectious disease, as it succeeded in compelling recognition of its distinctive epidemic

dignity, contended with its longer known rivals for historical precedence. The respective heralds of influenza, of poliomyelitis, of cerebrospinal meningitis, and of lethargic encephalitis have in turn claimed for the particular disease they championed lineal descent from the sweating and sleeping sicknesses of the Middle Ages.

Since these days medical science has demonstrated the existence of microbes and the means to identify them; has demonstrated that microbes are the agents that bring about infectious epidemics; that conditions of nutrition may enhance or depreciate both the average virulence of the epidemic agent and the average resistance of the community exposed to epidemic attack; and that epidemic invasion occurs when the average virulence of the microbic agent exceeds the average resistance of a conspicuous number of the members of any community where the microbe exists.

The mode of spread of the inciting microbic agents from one victim to another at the original epidemic area has been in part made clear to us. We recognize direct transmission of microbes from one vulnerable person to another, through contact either mediate or immediate. And we realize that persons who are not vulnerable or who are so slightly vulnerable as to remain ambulatory when attacked, and also more vulnerable victims at early and convalescent stages of the attack, may harbor the microbic agent and carry it within them. Through both animate and inanimate carriers epidemics may spread. The direction and extent of the spread of any epidemic depends partly upon the direction and extent of the dispersal from the original epidemic focus of the carriers of the microbic agent, and partly upon the resistance encountered by the microbic agent in the communities into which it is carried.

While medical science was discovering the cause of communicable disease and the manner of its diffusion, engineering science was placing every region of the globe in more or less intimate communication with every other region. As our knowledge of epidemics multiplied, steamships and steam engines multiplied also the channels by which epidemics might spread. At the same time clinical and bacteriological knowledge made us more sensitive to detect these diseases, even when they varied greatly from the usual type; and our professional zeal, with the instinct for self-preservation, combined to make us enemies of concealment, so that the universal aspect of an epidemic was made manifest as well as the national and the parochial. Hence, as the world became more liable to epidemics, more sensitive to detect them and more frank in disclosing them, epidemics tended to seem and to be more massive and more widespread than were their precursors in the Middle Ages. But so far as we know, epidemic succession throughout the centuries has been maintained unimpaired.

An organismal disease does not arise *de novo*. In this sense a new epidemic does not occur. There remains the possibility that an organism which for ages has been harmless to man may acquire characters pathogenic to man. Our knowledge of this possibility is too vague to permit of discussion. But we do know that microbic agents that only exceptionally affect human beings in certain periods may at other periods acquire power of attack to which only the exceptional human being of the time is immune; and that in our ignorance we have failed both to recognize the true nature of sporadic cases which have occurred among the exceptional, and to realize the true nature of epidemics. The ratio of the sporadic or epidemic cases to the total morbidity from infectious fevers may be taken as an index of the susceptibility of the population exposed to the exciting agent of the disease. This ratio sinks to insignificance in the quiescent intervals and rises to disastrous magnitude at epidemic periods. Three variables determine its value: one the organism; two, the host; and three, circumstances. Of these only the third is capable of sudden change. Throughout the ages weak strains of organisms and of hosts tend to perish, and the survivors to become modified to insure persistence. Such modifications doubtless imply adaptability on the part of the organisms and a tendency to protean forms suitable to protean circumstances. And in the host likewise the nature of the resistance tends to change in response to the changes in the method of attack. These changes on the part of the host are slowly acquired through generations of successful survival: on the part of the organism the change is more speedy and less fixed. A change in the circumstances governing the relations of the organism and its host, a sudden change in the biological integrity of the host such as arises in war with its famine and distress, confers a strategic advantage upon the more adaptable attack of the organism and a disastrous disadvantage upon the less adaptable powers of resistance of the host. Under certain circumstances one of the protean endemic forms of the organism prevails and flourishes and gives its character to the resulting epidemic. Under certain other circumstances, another form of the organism prevails. And as the circumstances change, one form may follow another, each attaining in unbroken sequence epidemic dignity. In the epidemic period that is now subsiding, as in so many similar periods in the past, war and famine existed over large areas of the earth's surface. In 1916 we were passing through one of a long series of minor and almost annual epidemics of poliomyelitis. To it succeeded in the war areas the epidemic of Spanish influenza. Then the first epidemic of lethargic encephalitis occurred, lasted about three months, died down and recurred. And now poliomyelitis is again prevalent.

From the accounts of the epidemics of long ago, from the events of the epidemic period from which we are now emerging, from the soft border that unites even if it separates influenza, poliomyelitis and lethargic encephalitis. It seems probable that these diseases are caused by the attack of organisms derived from the common protozoon stock.* It is well that we should collate all evidence of differences between these epidemic diseases. But it is

*I have already observed in the present epidemic of poliomyelitis among syndromes which are transitional between poliomyelitis and lethargic encephalitis unmistakable cases of poliomyelitis with the mental attitude of lethargic encephalitis and with lymphocytosis. (For example—Case A. B., spinal fluid, 149 cells to the cmm., 90 per cent. lymphocytes, excess of albumin and globulin and marked power to reduce Fehling's solution.)

also well that we should as carefully collate all evidence of their resemblances. And it is essential that we should investigate the factors which determine their epidemic rise and fall and sequence, for in knowledge of these factors alone lies the power of prevention.

129 East Sixty-ninth Street.

CHEMICALLY PURE ANHYDROUS DEXTROSE AS A THERAPEUTIC AGENT.

By WILLIAM H. PORTER, M.D.,

NEW YORK.

PROFESSOR EMERITUS IN PATHOLOGY AND INTERNAL MEDICINE AT THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THAT properly selected food prevents the development of pathological conditions or tends to remove abnormal states when present, is a theory long held by many able clinicians and internists. But that a particular food form may, in selected conditions, act to all intents and purposes as a definite therapeutic agent comes to most physicians as something, the verity of which requires definite demonstration.

And yet, on a strict basis of physiological chemistry, there is every reason to believe that recently there has been added to our armamentarium a food product which acts as a definite therapeutic agent, and which demonstrates marked utility in the treatment of a wide range of serious metabolic and assimilative disturbances. This product is a 99.5 per cent. pure anhydrous glucose, formed by the hydration of amylose from corn, acted upon by hydrochloric acid.

This method of production develops a product, identified as a $C_6H_{12}O_6$ compound, in which, as Haliburton intimates in connection with other forms of glucose molecules, there is a special molecular arrangement, differing from other $C_6H_{12}O_6$ forms in respect to the fact that there is an entirely different isomeric arrangement of the atoms. Likewise, in these corn sugar molecules, we have in all probability still another isomeric form of $C_6H_{12}O_6$ to deal with.

This difference is peculiarly manifest in the clinical results following the administration of this glycodextrose which are not comparable in the slightest degree with the results secured by the exhibition of $C_6H_{12}O_6$ derived by malting processes or from grains other than corn.

Nor does glucose, in the syrupy or gummy state in which it has been commonly known, seem to possess any properties approaching those peculiar to the glucose of the anhydrous crystalline product—probably because these various glucose molecules are entirely different isomers, with radically different properties.

So, in this article it should be remembered that we are dealing only with results secured from the administration of a chemically pure crystalline glucose molecule—as developed from the corn by a special process of hydration, a product which has a specific rotation $(\alpha)\ D^{20} = 52.7$, and is a pure dextrorotary sugar. This, I am inclined to believe, is identical with the end product, glucose, resulting from the complete digestion of the carbohydrates in the alimentary canal. This also contrasts with glucoses of indeterminate purity, with which we have become more or less familiar in the past, and which have caused those unfamiliar with physiological chemistry to condemn the use of glucoses generally. Yet, the conservation of digestive and dynamic energy, brought about by the special $C_6H_{12}O_6$ product, renders it immensely valuable, both from a dietetic and a therapeutic standpoint.

C. p. dextrose, as is obvious from a standpoint of chemistry, is readily burned and completely oxidized in the system, and apparently requires no expenditure of digestive or dynamic energy. For its complete combustion in the animal economy 100 grams of glucose requires the expenditure of 106 grams of oxygen.

The perfect utilization of the substance is proved by the fact that analyses of both feces and urine, repeatedly made by Prof. W. J. Gies, of the Columbia Medical School, and the writer, show in a large percentage of the cases examined complete absence of glucose, even after 8 to 10 ounces of the product have been added to the normal twenty-four-hour carbohydrate supplied to the patients in the ordinary food ingested. And many of these patients were in the most desperate pathological conditions.

In one instance 10 ounces of the glucose were dissolved in lemon juice and water administered in a single dose to an epileptic child of eight years, without producing the slightest untoward symptom, or without causing any of the glucose to "come over" in either the feces or the urine.

In certain rare instances, however, the glucose is not completely absorbed. In one case the specimen examined contained 2 per cent. of glucose. In none so far examined has any glucose been discovered in the urine, showing that when it is all absorbed it is fully utilized.

In the only two cases in which the glucose was detected in the feces, one patient was taking only 58 grams (or 1.865 oz.); the other 115.97 grams (or 3.729 oz.), showing that it was not the excessive amount of glucose taken which caused it to escape in the feces. For both these patients had repeatedly taken more than this amount without any appearance of glucose in the feces, and have since taken larger amounts without it appearing in the feces or urine.

The explanation probably lies in the fact that in one case there was a decided disturbance in digestion, with probable imperfect general absorption; while in the other there was decided depression of the nervous system. This, reacting upon the digestive system, probably accounted for the non-absorption of the glucose in these two instances.

On the other hand, bottle babies utilize the glucose perfectly, as Professor Gies has shown by repeated examinations of urinary and fecal specimens from the service of Dr. R. G. Dennett, of the Post-Graduate Medical School and Hospital.

The fuel and energy value of this product can best be understood when it is remembered that each 100 grams of this glucose, when completely oxidized, yields 146 grams of CO_2 and 60 grams of water, furnishing 401 large calories of heat. For the most complete oxidation reduction within the animal economy it must be remembered that the fluids and tissues must be kept all the time in a state of high alkalinity.

Of course, the nutritional value of the glucose lies

in its yield of heat and its stimulation of dynamic energy, as glucose does not contribute to the constructive work of the human economy; this being, as is generally admitted, accomplished only by the utilization of protein and by the inorganic salts.

Sugar the Kindling That Starts the Fire Under the Fat.—However, by the production of heat and dynamic energy, the glucose causes a more complete combustion of fats, and consequently decreases the tendency toward the formation of lactic, oxybutyric and other organic acids, as well as the acetone and acetone-forming conditions, commonly found in connection with the condition called acidosis, but which in reality is a state of decreased alkalinity.*

It must always be remembered that there are two forms of the so-called acidosis condition, depending upon the causative factors. One is due to an imperfect supply of the disodic-monohydrogen-phosphate. The other has, in addition to the depletion of the alkaline salts, an insufficient supply of glucose, with an oversupply of protein matter. This latter condition results in imperfect combustion of the fats, followed by a decomposition of proteid substances, the formation of acetone, acetone bodies, and oxybutyric acid. Hence the treatment differs. In the former condition all that need be done is to reestablish the supply of the normal alkaline salts. In the latter the proteids must be cut down and glucose somewhat freely administered.

There is no doubt but that the glucose also prevents the too rapid oxidation of protein, and hence becomes in a sense a conservator of tissue waste, arresting retrograde tissue metamorphosis. At the same time we must not lose sight of the fact that decreased protein oxidation always means a decrease in heat production from this source, proportionate to the decreased protein metabolism.

For when there is complete oxidation of the protein elements, with normal end products, instead of the abnormal catabolism which predominates in retrograde tissue metamorphosis, there is a more complete combustion of the proteid elements. This, in a measure, compensates for the decreased utilization of these products, and thus makes good the loss of heat.

In this connection it may well be emphasized that the present-day attempt to compute food values exclusively in terms of calories is a fallacy, inasmuch as no method of food measurement by heat units can adequately—or even inadequately—estimate the complex metabolic processes functioning in the animal economy. And these especially must most certainly be reckoned with if the true significance of the utilization of food is to be understood.

Having suggested the probable philosophy of action of c. p. dextrose or glucose, it might be pertinent to cite a few instances of what might be termed its therapeutic activity, illustrating, by clinical reports, the efficacy of this food form when added to the normal diet.

This activity is especially striking when it is remembered that, in no instance, was there any change made, either in the diet or in the medication, which would explain the almost uniform improvement noted in the patients on whom this "treatment" was tested out. The only change was to add from 12 to 24—and on some days as high as 48—teaspoonfuls of anhydrous glucose to the prescribed diet and other medication, or 111.97 grams (3.6003 oz.) to 229.5 grams (7.365 oz.)

The Death-Marked Heart Case.—One of the most striking cases treated was that of a woman past 60, who had suffered from cardiovascular disease for more than eight years. During most of this time she was able to attend to her rather light duties as librarian in one of our local libraries. On January 27, 1920, she developed a severe attack of influenza, from which she did not recover until the first of March. Against advice, she returned to her duties before she had thoroughly convalesced, with the result that, at the end of two weeks, she had to give up work. On April 28 she had a number of pyorrhoic teeth extracted, on the assumption that her trouble might possibly be aggravated by focal infection absorption. As a consequence, for the following two weeks, she was able to eat but little, which still further depleted her rather meager store of vitality. Strength and resistance decreased rapidly. Dyspnea due to cardiac exhaustion developed. This was accompanied by terrific precordial pain, simulating a true angina, but centering deep in the chest. On the 29th of May the patient had a very obstinate attack of constipation, with high autointoxication together with a decided increase in the dyspnea, and in the periodic attacks of pain. Dropsy then set in, starting in the feet and ankles, and gradually extending as far as the shoulder blades.

About this time she developed that peculiar reaction to which I have called frequent attention during these past ten years, which consists in the application of the indican test, as described in this article.

The Porter Metabolism Test.—This test, when properly applied and interpreted, also determines the state of the metabolism—whether perfect or imperfect—and also shows the degree of imperfection. For in nearly all the patients in whom I have observed it this reaction indicates a fatal termination of the illness. This peculiar reaction is noticed in connection with the ordinary indican test. It develops as a result of adding equal quantities of urine and chemically pure hydrochloric acid in an ordinary test tube, then adding 8 to 10 drops of ½ per cent. solution of permanganate of potassium, and then—depending upon the size of the test tube—from ½ to 1 dram of chloroform. This test requires from twenty-four to forty-eight hours for its full development, which emphasizes the inadequacy of this metabolism test when superficially and hastily made.

When dissolution is imminent a peculiar flocculent material develops in association with a fairly large amount of indican, or even in the absence of indican, shading in color from a light gray to almost black. This flocculent and oily matter is often observed in the absence of any indican. This flocculent substance, upon microscopic examination, is found to be composed of two distinct types of material—one part consisting of fine granular matter, which, when very abundant, masses together and collects above the level of the chloroform.

The other substance is composed of this same granular material, in conjunction with numbers of large and small globules, resembling fat globules under the microscope. When the latter predominates it collects as a white, snow-like mass, which seems to fall below the level of the junction of chloroform and urine. When the light gray flocculent material forms above the junction of the chloroform and urine, numerous fat-like globules are present in

*Porter, Wm. H., The Therapeutics of Decreasing Body Alkalinity, MEDICAL RECORD, September 18, 1920, p. 471.

some instances, in conjunction with or enmeshed in the simple granular matter.

When this flocculent matter is dark and solid it is usually composed entirely of this granular material, the fat-like globules being absent, thus explaining the various range of colorations which is observed in conjunction with the application of this test. When this matter is very dark and abundant, and formed rapidly and is seen above the level of the chloroform, death is likely to ensue within a very short time. On the other hand, when the flocculent ring is white and "snowy" like, and beneath the level of the chloroform, it indicates varying degrees of disturbed metabolism, depending upon the depth and the density of the ring.

This granular material is probably some form of protein of a colloidal character which has undergone a beginning fatty degeneration, the granulation being due to the large number of and the extreme minuteness of the particles. I might add that the granular material is only partly soluble in ether, as it seems to retain its identity in distinct contrast to the droplets. I have observed that the nearer the patient is to death, the more rapidly the flocculent ring tends to form. This ring may be from ½ to even an inch in height, and, unless it can be diminished or removed by radical and appropriate treatment, death inevitably follows.

Dr. W. J. Gies' report on this peculiar urinary product is as follows: "During the course of this work, you called my attention to a peculiar precipitation you had frequently obtained in applications of the ordinary chloroform-acid test for urinary indican. You observed, you said, that, when such mixtures (that is, urine, hydrochloric acid, a weak solution of permanganate of potassium and chloroform) were allowed to stand, a heavy dark floculent precipitate collected above the chloroform in the urines of the patients suffering from nutritive disturbances who were approaching a fatal termination, but did not appear under similar conditions in the urine of normal people, or of patients whose diseases did not involve serious nutritive disorders. You also stated that a white oily precipitate frequently appears in such mixtures in the upper part of the chloroform *but within the range of the chloroform layer,* this precipitate showing special tendency to adhere to the side of the vessel in which it is separated.

At your request, and because of your desire to determine the effect of administering dextrose on the conditions responsible for the occurrence of the phenomenon, I endeavored to determine the nature of the dark precipitate that forms, under these conditions stated, immediately above (and that rests upon) the chloroform. You sent me urine from several of your patients for this purpose. I found that this substance is a modified form of coagulable protein and that it consists of a mixture of modified albumins and globulins, presumably from the *blood* of the individual affected.

I have been unable to obtain enough precipitated material to determine satisfactorily the character of the white precipitate that frequently is produced in the uppert part of the chloroform zone, under the conditions stated above.

In making tests for dextrose and other constituents of the excreta, I used routine procedures for the effective quantitative detection of small quantities and for the accurate quantitative determination of minute amounts."

It may be noted that while there was no active kidney complication in this heart case, there were, nevertheless, two parts of albumin to the thousand, estimated by the Esbach tube.

This patient had been receiving the usual remedies for dropsy, pain, and dyspnea, in addition to general stimulant measures, notwithstanding which she was steadily losing ground, day by day, although she was eating fairly well.

On the 13th of June, I began giving her eight grams of this chemically pure anhydrous dextrose every two hours. This immediately produced a very decided change for the better. The output of albumin decreased 75 per cent. within 48 hours, and did not rise again so long as the patient was taking the sugar. Pain and dyspnea were less intense, and the condition generally assumed a more favorable aspect. The dropsy also markedly decreased. In fact, all symptoms showed definite improvement.

On the 25th of June the limited dextrose supply was exhausted, and for four days the patient was without sugar. During these four days it was apparent that she was rapidly losing the ground she had gained. The albumin immediately jumped back 75 per cent. to its old mark, while the dyspnea and the general symptoms were aggravated.

On the 29th of June another supply of the anhydrous glucose was obtained. Within 24 hours the patient evidenced improvement in all symptoms. The albumin immediately dropped 75 per cent.—as it did when the glucose was first administered—and has remained at this figure ever since. The peculiar "death line" reaction in the urine decreased, until finally it disappeared. Digestion and assimilation became apparently normal once more. The patient at the end of three weeks was relieved of all distressing symptoms, and was sufficiently recovered to be able to take a one hundred mile trip into the country, which trip she bore very well indeed. After a few weeks she returned to town much improved.

While it is possible that she may never again be entirely well, yet it is clearly evident that, from all indications, she bids fair to live for many years in relative comfort, although she will, no doubt, be obliged to take this dextrose for the remainder of her life, which, by the way, cannot in any sense be construed as a hardship.

In a number of other cases of varying types of disturbed metabolism in which the sugar has been administered in doses ranging from 8 to 12 grams every two hours, there has been a uniform and decided improvement, manifested sometimes within forty-eight hours. Not only have these patients objectively appeared better, but the urinary findings have also shown a definite improvement, demonstrating a better oxidation, apparently as a direct result of the complete utilization of the sugar. For in none of these cases was either the diet or the general medical treatment changed. One very aggravated case of diarrhea of several weeks' standing, which had refused to respond to various lines of treatment, yielded quite readily to the general physical improvement which followed the perfect utilization of this c. p. dextrose.

One of the patients gained 3½ pounds the first week, while a chronic skin eruption from which he had suffered for many months seemed materially improved. Another has gained 7 pounds in a month, and reports a decidedly increased resistance to fatigue, together with a greater capacity for sustained mental and physical effort. The nervous sys-

tem also shows more stability, as evidenced by a lessened phosphaturia. Most of the cases treated seem to develop a better color, as well as an increase in the appetite and in the capacity for assimilating food.

One obese patient has lost 4 pounds, due possibly to an increase in the capacity of the system for oxidizing fat; and one case of chronic catarrh of years' standing has been wonderfully improved.

While, of course, I realize that this dextrose has been used in what might be called a comparatively small number of cases, and over only a relatively short period of time, yet the very pronounced improvement in the cardiovascular case, and in the severe case of diarrhea, and the uniform improvement among the sixty or seventy patients to whom the glucose was administered, leads me to believe that we have in this particular isomeric type of molecule a therapeutic agent which, when more extensively and universally used, will prove of inestimable value in the management of many profound disturbances of metabolism.

I may say that in one or two cases on whom the dextrose was tried there were some evidences of a lack of toleration for this sugar form—manifested in gastric and intestinal disturbances of a transient character, which perhaps is only to be anticipated when dealing with a factor in which idiosyncrasy plays such a prominent rôle.

I am also convinced that this sugar is better oxydized—as, in fact, is any food product—when the fluids of the body are kept in a *high state* of *alkalinity*, and the oxidation reduction of all food products is facilitated.

Glucose Already Well Established as a Surgical Measure.—I am, of course, well aware that Woodyatt, Erlanger, and many other physiologists in this country, as well as in France, Italy, and Austria, have had some exceedingly interesting results with glucose, administered intravenously, and that there is a fairly ample literature concerning the successful subcutaneous and rectal use of the sugar. I am familiar also with the researches conducted in Germany, both in infant feeding and in wasting diseases, as well as in cardiovascular conditions. Also in the treatment of glycosuria, detailed by Grafe (*Münch. med. Woch.*, 1914, lxi, 1433), in which are reported twenty-five cases of diabetes treated with carameled grape sugar, using enough dextrose to produce some 600 to 800 calories, 147.32 grams (4.4737 oz.) to 195.12 grams (6.3085 oz.). All these cases showed a beneficial action on the acidosis, and without increasing the glycosuria. I have verified Grafe's results in all the diabetic cases in which this particular product has been administered.

I feel rather certain, however, that the present is the first extended investigation made in this country with this particular sugar form. This is chiefly for the reason that c. p. anhydrous dextrose has not hitherto been available, except in small quantities for research and laboratory work, or in fractional amounts imported from Germany at almost prohibitive cost.

From what I have seen of the action of this food form, however, and from the preliminary reports furnished me by some of the leading pediatrists of New York, at present conducting an elaborate series of experiments as to its value in infant feeding, the details of which will later be presented in full from their own viewpoint, I feel strongly that we have in this anhydrous dextrose an agent which bids fair to revolutionize the treatment of many conditions now considered grave—or even hopeless.

And what pleases me quite as much as anything else in connection with this matter is the fact that the result of administering this sugar proves what I have consistently contended for forty years, *i.e.*, that food, properly selected and administered, can be made a therapeutic agent second in importance to nothing else in the U. S. Pharmacopœia.

46 West Eighty-third Street.

WHAT IS AN INTOXICATING BEVERAGE?*

By CHARLES A. ROSEWATER, M.D.,

NEWARK, N. J.

CAPTAIN MEDICAL RESERVE CORPS, U. S. A.; DELEGATE FROM NEW JERSEY TO THE FIFTEENTH INTERNATIONAL CONGRESS AGAINST ALCOHOLISM.

The Supreme Court of the United States has spoken and upheld the constitutionality of the Eighteenth Amendment and the National Prohibition Act, and has decided that Congress has the power of defining what constitutes an intoxicating beverage as a matter of law, regardless of whether or not such beverage is intoxicating as a matter of fact. The question, What is an intoxicating beverage? can therefore now be studied scientifically and free from the bias attending one's views upon the question of prohibition. The question is of particular import at this time, for an eminent authority, credited with having been the author of the National Prohibition Act, has issued a statement to the effect that while the National Prohibition Act expressly prohibits the manufacture for sale of beverages containing as much as one-half of one per cent of alcohol, this restriction does not apply to cider and other fruit beverages made in the home for home consumption. He states that the legal limit of alcoholic content in these home-made beverages is the quantity or percentage of alcohol which will make the beverage intoxicating in fact. As multitudes of homes are being converted into miniature distilleries, wineries, and breweries, and oceans of alcoholic beverages are being produced from numberless formulæ, the question above propounded will naturallly and properly be referred to the physician for answer. Hence this communication.

In attempting to define an "intoxicating" beverage, we are at the outset confronted by the fact that we possess no unit of intoxication, no definite or positive guide as to whether a man is or is not intoxicated. The question is on a par with the one, What is a poison? For example it is well known that common salt is indispensable to life, yet this substance is used in China as the popular method of committing suicide, for when taken in sufficient quantity, salt is highly poisonous and will produce a violent gastroenteritis and may cause death.

We not only possess no unit of intoxication, but we do not always use the term "intoxication" in the same sense. It seems clear however that in

*Read by title at the 154th annual meeting of the Medical Society of New Jersey, Spring Lake, June 15, 1920.

discussing beverages which will cause intoxication, the word is used in its natural and accepted sense and is synonymous with drunkenness. Any other interpretation of the word, such as the farcical attempt to make the term cover "invisible intoxication," would of necessity include not only alcoholic beverages, but such substances as coffee, tea, coca cola, etc.

To meet the difficulty presented by the absence of suitable definitions, the following definitions have been suggested:

"Intoxicating liquors are those liquors which are intended for use as, or capable of being used as, beverages, and which contain alcohol in such proportion or per cent that when consumed in any quantity that may practically be drunk by an ordinary man, or in any quantity that the human stomach can ordinarily hold, will produce a condition commonly known as intoxication or drunkenness. Drunkenness or intoxication is a materially abnormal mental or physical condition, manifesting itself in the loss of the ordinary control of the mental faculties or bodily functions to a substantial extent."

It was with these definitions in mind that the writer and others conducted a series of tests with alcoholic solutions to determine whether or not they are intoxicating in fact. The materials tested were beer with an alcoholic content of 2.75 per cent by weight, and a watery solution of the same alcoholic strength.

While volumes have been written upon the subject of alcohol, it is remarkable that other than the work herein referred to, all of which has been done within the past year or so, that there are practically no data available as to the effects of alcohol in dilute solution and in combination with food substances. Blood studies in alcoholism, conducted by Schweisheimer some years ago, confirmed the belief that intoxication does not occur until the amount of alcohol in the blood reaches a certain degree of concentration. He found in one case of mild intoxication that the blood contained 0.153 per cent of alcohol, and in a case of severe intoxication he found 0.227 per cent. The writer, in association with Dr. Stephen P. Jewett, found in a case of marked intoxication, 0.196 per cent of alcohol in the blood.

With these facts to guide us we at first directed our attention to determine the amount of alcohol which appears in the blood after the drinking of various amounts of beer with an alcoholic content of 2.75 per cent by weight. The blood tests were made by Dr. John Marshall at the University of Pennsylvania laboratory, and by Dr. William John Geis at the New York College of Physicians and Surgeons. Dr. Marshall's subjects were three medical students, extremely moderate in the use of alcohol. Subjects 1 and 2 each drank 1200 c.c. of beer at one time, containing a total quantity of 41.88 c.c. of alcohol. Six specimens of blood were taken from each subject at intervals during a period of about seven hours. The highest degree of concentration of alcohol in the blood of either subject was 0.035 and the lowest point was 0.0075 per cent. Subject 3 drank in about two hours, 1,774 c.c. of beer, containing 61.9 c.c. of alcohol. In subject 3, the highest point of concentration was reached about one hour after the tests were begun, when it was found to be 0.015 per cent, and it was observed that the amount of alcohol in he blood grew less as the drinking continued, being 0.0075 at the conclusion of the experiment.

Dr. Geis experimented with two men and three women. Two of the women were practically total abstainers. The tests made by Dr. Geis confirmed the work of Dr. Marshall and proved conclusively that with forced drinking of beer containing 2.75 per cent of alcohol, the alcohol content of the blood was far below the amount found by Schweisheimer in a mild case of intoxication.

In 1910, Widmark (*Skandiv. Archiv f. Physiologie*, vol. 33, p. 85), published an interesting contribution to the subject of alcohol absorption in which he made the assertion that the amount of alcohol which appears in the urine after taking alcohol, is about equal in amount to that which appears in the blood. We therefore directed our attention to the study of the alcohol content of the urine after drinking beer containing 2.75 per cent of alcohol by weight. The subjects were two college students who were practically total abstainers. They each took 50 ounces of beer in one hour, taking at fifteen minute intervals the contents of a 12½ ounce bottle. Three specimens of the urine taken at intervals for two hours thereafter showed an amount of alcohol practically the same as that reported by Dr. Marshall in his experiments.

The mental processes as affected by dilute alcohol were studied by Prof. Harry L. Hollingsworth, associate professor of psychology at Columbia University. He experimented with beer containing 2.75 per cent by weight of alcohol, and, for purposes of control, used beer containing no alcohol. His tests were most elaborate. The six subjects used ranged from total abstainers through occasional and moderate users, to a fairly regular but not excessive user of alcoholic beverages. They ranged in age from just over twenty-one years to nearly thirty years, and several of them had seen army and navy service. The doses of beer ranged from three 12½ ounce bottles (the capacity of the average adult stomach) to the maximum amount which the heaviest of the six drinkers could consume in a period of 2½ hours. The processes tested and measured ranged from simple tests of motor speed and the reflex involved in the heart beat, through processes involving steadiness of arm and hand, coordination of eye and hand, control of speech processes, forming of simple associative bonds in learning, up to the higher mental processes involved in reacting to logical relations, and in mental calculation. Professor Hollingsworth has summarized the results of his investigations as follows: The effects are most marked in steadiness and in mental calculation. They are next most conspicuous in tapping, in learning, and in naming opposites; and least of all in coordination and in color naming. The maximum influence on the score, that shown in the steadiness test, is only half as great as the influence on this same function of the amount of caffeine contained in two ordinary cups of coffee, and the unsteadiness produced by three or four bottles of beer is approximately equal to that produced by a hearty meal. The striking effect on the pulse rate is considerably less than the similar acceleration that ensues after eating a hearty meal. The influence of the beer on

the remaining processes is entirely comparable in amount (atlhough in some cases different in direction) to the effect produced on the same processes by the amount of caffeine contained in two ordinary cups of coffee. There were none of the symptoms commonly associated with alcoholic intoxication—no falling down, no staggering, no obscenity, no personal untidiness, no fighting, and three of the subjects showed no signs to expert observers of having taken liquor at all.

For the purpose of testing the amount of alcoholic liquids in dilute solutions which it is possible for a man to imbibe within a period of several hours, and for noting whether or not the effect is cumulative under conditions of forced drinking, Dr. Edward M. Pemberton, at the University of Arkansas Medical Department, conducted a series of experiments upon men, most of whom were students and total abstainers. The fluid used was a watery solution of alcohol, 2.75 per cent by weight. Dr. Pemberton made eleven experiments. The ages of the subjects were between twenty and thirty years, one was thirty-six and one fifty-four years of age. The time was about five hours, and the quantities consumed ranged from two quarts to over seven quarts. Dr. Pemberton arrived at the following conclusions:

"At the conclusion of the experiments each of the subjects expressed confidence that he could not hold enough of the 2.75 per cent alcoholic fluid to become intoxicated. This was likewise the observation of the experimenter. Symptoms which appeared during the course or at the conclusion of the experiments were due either to the pressure of the fluid in the stomach or to the reflex stimulation of the alcohol, that is due to the local effect of the alcohol upon the mucous membrane of the throat and stomach before absorption, and consequently before it enters the blood and is taken up by the tissues. This reflex is not systemic and not cumulative, and tends to become less and less. In no instance were the reflexes, conversation, or locomotion of the individual other than normal at the conclusion of the experiment.

The Pemberton experiments indicate that there is a limit to the amount of fluids which the tissues will absorb. Just as a sponge will soon reach its capacity for absorption and cease absorbing, so the human tissues will cease for a time to absorb, after the point of satiety has been reached. Were this not a fact, it would be possible for an individual to drown himself by drinking water.

To determine whether or not an ordinary man can drink enough beer with an alcoholic content of 2.75 per cent by weight, to render him intoxicated, practical tests were conducted by the writer. The subjects were tested in two groups. The first group consisted of thirteen men and comprised mechanics and brain workers between the ages of twenty-three and sixty-six years, representing various types of drinkers. They were furnished with highly seasoned food to stimulate thirst and were encouraged to drink as much beer as they could during the test. The second group comprised men engaged in mental work. They were between the ages of thirty-three and forty-five years, were all extremely moderate users of alcohol and took beer only rarely. They were furnished a regular dinner without soup and were urged to drink as much beer as they could during the four hours of the test. The quantity of beer consumed by the individuals in the tests ranged from 36 ounces to 187 ounces per individual.

Summarizing the results of the test dinners, the experiments lead to the following conclusions:

1. The drinking was forced. Every man drank more than he would have ordinarily drunk had he not been participating in a test.
2. The beverage tested does not compel repetition.
3. Satiety was complete and rapid. The subjects stated that they felt bloated and that further drinking would add to their discomfort.
4. Several of the subjects had been drunk on previous occasions from strong alcoholic preparations, thus showing that they were not immune to drunkenness.
6. Not one of the subjects manifested the slightest signs of intoxication.

A most illuminating contribution to the subject under consideration was published by Edward Mellanby, Professor of Physiology in the University of London (*British Journal of Inebriety* for April, 1920), who conducted an exhaustive series of experiments for the British Control Board. From his work I make a few quotations.

"The alcohol in the blood is at a maximum about one hour from the beginning of the experiment, whereas even nineteen hours later there is still a trace of alcohol left in the blood. . . . Probably in twenty-one hours the blood would be free from alcohol. . . . In fact it can generally be stated that any conditions which depresses the point of maximum concentration in the blood has a great effect in depressing the maximum intensity of intoxication. . . . Except with small quantities of alcohol, the amount in the blood at the maximum points is roughly proportional to the amount drunk. . . . It will be seen that although the amount and strength of the alcohol in the diluted whisky and the stout are the same, yet the whisky alcohol was still more rapidly absorbed. The probable explanation of this result is that stout contains something which slightly inhibits the absorption of alcohol. . . . You can see therefore how difficult it would be to produce a real intoxication with a 3 per cent ale when only a limited amount of time is allowed for drinking. Whereas it is possible for a man to get intoxicated almost to a moribund condition if allowed five minutes with a whisky bottle, the ordinary man could not approach this state if allowed complete freedom of action for four hours surrounded by unlimited 3 per cent ale."

While the foregoing is based upon comparatively few experiments, the results are corrobative of the sociological experiment on a national scale which for some years now has been going on in Norway. In that enlightened land, the people of which are held up to us as models of "sobriety, righteousness and thrift, presenting a refreshing contrast to the unrest of our own country" (Nammack), there is sold, with practically no restriction, beer with an alcoholic content of 2.75 per cent by weight (3.50 per cent by volume).

It would therefore appear that disregarding all fanciful theories and hair splitting definitions and considering all the facts, the seeker after truth, viewing the matter in the broad light of common sense, can safely state, with all reasonable degree of

certainty, that a beverage containing as little as 2.75 per cent by weight of alcohol (practically 3.50 per cent by volume) is not an intoxicating beverage.

40 MILFORD AVENUE.

THE TREATMENT OF CERTAIN GYNECOLOGICAL DISEASES WITH RADIATION.

BY J. THOMPSON STEVENS, M.D.,

MONTCLAIR, N. J.

FELLOW OF THE AMERICAN ROENTGEN RAY SOCIETY.

RADIATION is being used with marked success in several different parts of the world in the treatment of some of the diseases peculiar to women. Among these diseases which are managed so successfully with radiation are: Cancer of uterus, subperitoneal and intramural fibroids, menorrhagia and metrorrhagia without demonstrable pathology, and amenorrhea.

Cancer of the genital tract appears in three clinical forms: (1) Operable, (2) Inoperable, and (3) Borderline cases.

A cancer of the pelvic organs that is operable should be extirpated, for by removing the new growth we get rid of the source of infection. But our responsibility does not end once the operation is completed and the last surgical dressing has been done. We must use every means at our command to prevent recurrence in the future. Some cases will develop recurrences no matter how we manage them, but a larger percentage can be cured definitely if we devote a little of our attention to the prevention of metastasis. This, we can generally do by subjecting the patient to a careful, thorough course of ante-operative radiation and exhaustive postoperative radiation.

In the case of an operable cancer it is rarely possible to find by ordinary methods of examination any evidence of metastasis. The large percentage of recurrences following operation is however proof that metastases had already taken place, but that we had failed to find them. Careful roentgen examination of the abdomen (both anterior and posterior plates) must be made; the spine and the hip-joints must be carefully examined for evidence of early metastasis. If metastasis is demonstrated we are now in a position to attack it with some hope of final cure.

We know that pathological tissue is about five times less resistant to radiation than is normal tissue and that the application of seven doses of the rays is usually sufficient to stop proliferation in a growth four inches below the surface. We now proceed to cover the front, back and both sides of the pelvis with the roentgen rays, giving through each area treated as much of the rays as the normal tissues can stand. The tube is so tilted over each area that the rays are passed directly into the growth. The filtration that the rays are subjected to by the thick tissues of the pelvis and the bones in the neighborhood makes it necessary for us to treat through more than seven areas. A stout patient will have a greater skin surface, so that we can make up for the increased filtration by treating through more areas. For the usual case from six to ten areas in the front and from four to six in the back are generally sufficient for cross-firing directly onto the growth through each area. Any nodules found in the roentgen examination will have to be crossfired upon through a varying number of areas according to their depth. Sometimes we must cover the entire abdomen, and it is well to go even above the diaphragm, front, back, and both sides. This is a most trying ordeal for both the roentgenologist and his apparatus, as it is apt to take from six to eight or more hours of continuous operation. Because of the nausea and ill-being produced by such intensive treatment it is usually advisable to treat through from four to six areas on successive days until the patient is entirely covered. It is my method usually to treat the more distant areas first, working gradually toward the disease, and finally at one sitting doing the front and back of the pelvis from the navel to the pubis. I consider this method of beginning outside and working toward the growth of great importance in the prevention of metastasis. By such a method it is easily seen that the patient comes up for operation with the cancer cells of lowered vitality and many of them actually destroyed. The patient should be operated upon within twenty-four hours following the last series of radiations.

Physicians and surgeons throughout the world are beginning to realize more and more that a palliative operation is seldom if ever indicated in the cases that are inoperable and those that are questionably operable, and are advising against palliative operations. They know that operations in these cases serve only to relieve for a short time and really hasten the end. These are the cases that should have the advantage of radiation, too. Some of these cases are soon made operable, and some of them are cured by radiation alone. In this class of cases we must be very exacting in our technique. Sometimes the entire body will have to be covered. The entire abdomen must always be covered—front, back and both sides. We must push treatments to the limit of tolorance. Under such treatments the skin will be tanned, and in those cases that are easily tanned we generally get the best final results.

When possible we should always add radium treatments to our roentgen treatments. This can be done in the interval between the roentgen treatments. The radium can be applied directly to the growth in many cases, *i.e.* those that are intrauterine and within the cervix according to the indications. However, it is my opinion that we should never limit our radiations to radium alone, but must also in all cases use the roentgen ray. It is well known that the mortality is higher when radium alone is used than when the roentgen ray alone is used, and that the lowest mortality is obtained when both agents are used. The radium exposures will have to vary according to the amounts of radium available. Nearly all agree that better results are obtained when fairly large amounts are used with shorter exposure than when smaller amounts of radium are used with longer exposure. Whenever possible not less than 200 milligrams should be used, allowing an exposure of 1400 or more milligram-hours as indicated.

Technique: We must have a transformer with a capacity of a backup of the equivalent of 90,000 volts, a broad focus, universal type, Coolidge tube,

and a tube holder that will permit us to bring the target of the tube eight inches from the skin. Over each area we produce an erythema. This is done by letting the tube draw five milliamperes for five minutes according to the pastile. Administering the rays through six millimeters of filter, however, allows us to increase our dosage up to forty milliampere minutes over each area and in some cases as much as seventy-five milliampere minutes may be used over each area. Over each area we crossfire directly onto the growth. After having covered the body, front, back, and both sides, we have completed one series. The entire series is repeated at about monthly intervals, according to the condition of the skin for six or more times as indicated.

Subperitoneal and intramural fibroids, except those that have undergone calcification, are most favorably influenced by the roentgen rays. The radiation method of treatment appeals to many patients because of the fact that it is done without an anesthetic, without a stay at an institution or a hospital, without any pain, and without taking the patient from her duties. The results obtained compare most favorably with other methods of treatment. The hemorrhage will sometimes stop entirely after the first series of treatments, but generally it requires from two to three series before the hemorrhages are entirely controlled. Often the tumor will have disappear9ed by this time, but generally it will require from four to six series of treatments before its complete disappearance.

In the past it was thought that some functional disturbance in the ovaries determined whether or not a fibroid would appear, and so the ovarian region was usually radiated, too. Since this time, however, Pfahler and others have proven beyond doubt that the trouble is limited to the uterus alone. Treatment of the entire pelvis commonly resulted in the permanent suppression of the menses. Nowadays the uterus with its tumor is crossfired upon until the desired result is obtained without producing more than a temporary disappearance of the menses, leaving the patient in a condition to bear children. What more can be obtained with any other method of treatment?

Technique: Set the machine so that it will back-up the equivalent of 90,000 volts, and administer to each area from twenty-five to forty milliampere-minutes at a focal distance of eight inches through six millimeters of filter material. Repeat at about monthly intervals from four to six times. We must keep in the midline and must protect the areas normally occupied by the ovaries with thick sheet lead, otherwise we may produce a permanent amenorrhea.

Menorrhagia and metrorrhagia without demonstrable pathology, the cases that have been curetted and treated otherwise without success, can generally be cured with one series, two at most, of highly penetrating roentgen rays. This is a most acceptable method of treatment to surgeon, physician, and patient. In these cases about the only other method of successful treatment is hysterectomy. Many of these patients are really so ill from the loss of blood that hysterectomy could hardly be expected to yield the results that we have a right to expect, *i.e.* to save life. Here the roentgen rays have first call. The results obtained with radium do not compare in the least with those obtained with the roentgen rays. With correct technique we should cure 100 per cent. We should not attempt the treatment of menorrhagia and metrorrhagia that is thought to be due to a congestive endometritis caused by displacement of the uterus, but should subject these patients to surgery. If replacement and fixation of the pelvic organs is not successful in stopping the hemorrhages then we can look to the roentgen rays for help.

In these cases we shall have to decide just what result we would like to obtain before the treatments are started. If the patient is young, we ought not to produce a permanent amenorrhea unless we have to. We should carefully protect the regions normally occupied by the ovaries with thick lead sheets and then crossfire toward the uterus through the midline of the pelvis from navel to pubis front and back. If the patient is past middle life then we may produce a permanent amenorrhea by treating the entire pelvis, first explaining the whole matter to the patient.

Technique: Same as for fibroids.

We have seen how the roentgen rays will stop proliferation and will finally destroy new growths, both benign and malignant. They will also stimulate cells that are below par to functionate in their normal manner. In those cases of irregularity and infrequent periods in young women we can offtimes bring about a normal state by the application of a stimulating dose of the rays to the ovarian region. Often in these cases the hemoglobin is not up to the normal standard, but gradually increases following roentgen treatment, probably through some action of the internal secretions liberated by the rays.

Technique: Exposure in one area over each ovarian area with the same setting as for fibroids. A stimulating dose consists of ten milliampere minutes.

CASE I.—Mrs. C. A. C. came to me for palliative treatment of an inoperable growth in the pelvis. Examination showed that she had lost sixty-one pounds in four months and that the entire pelvis was filled with an immovable mass at least as large as a baby's head. Roentgen examination failed to show any evidence of metastasis above the false pelvis.

Technique: Transformer set to back up the equivalent of 90,000 volts, 6 millimeters of filter, 8 inch focal distance, fifty milliampere minutes over each area from navel to pubis and a like area over the back. Repeated every month for six months. No treatment since.

Result: There has been no hemorrhage since the second series. Uterus is normal in size and is freely movable. Roentgen examination shows no evidence of recurrence anywhere. She has gained seventy-two pounds since the last treatment, two years ago, and is in perfect health.

CASE II.—Mrs. P. S. C. was sent to me for roentgen treatment of a subperitoneal fibroid arising from the fundus of the uterus posteriorly. The tumor was easily palpated and appeared to be about the dimension of a medium sized orange. The patient complained of severe menorrhagia and metrorrhagia. Roentgen examination showed that the tumor had not undergone calcification.

Technique: 90,000 volt back-up, 6 millimeters of filter, 8 inch anode-skin distance, forty milliampere minutes, over each of six areas in the front and four in the back, crossfiring onto the growth; repeated four times.

Result: The patient stopped bleeding two weeks after the first series and has seen no blood since. The tumor is now hardly palpable.

CASE III.—Mrs. C. A. N. was sent to me for roentgen treatment of menorrhagia and metrorrhagia. The patient usually flowed from twenty to twenty-five days out of each month. Physical and roentgen examination failed to show any cause for the hemorrhages.

Technique: Equivalent of 90,000 volt back-up, 6 millimeters of filter, 8 inch focal distance, forty milliampere minutes over each of six areas, three in the front and three in the back, keeping well within the midline of the pelvis.

Result: The month following the one series the patient had no flow at all. Two months following the one series the flow appeared, lasting five days and saturating two napkins daily; no pain whatever. For the next six months patient had six like periods and at the present time she is five months' pregnant.

CASE IV.—Miss M. S. came to me with the following history: At the age of fourteen she had a normal period, her first; none since in four years. The patient complained of ill-being about every month regularly. Her face would "break out" and she was very nervous. Examination showed the hemoglobin to be 40 per cent., otherwise nothing abnormal was found.

Technique: Equivalent of 90,000 volt back-up, 6 millimeters of filter, 8 inch focal distance, ten milliampere minutes over each ovary once.

Result: The month following treatment the patient had a normal period. Since then she has had eight more normal ones. Hemoglobin 87 per cent. No treatment except roentgen. All symptoms have cleared up most satisfactorily and the patient has gained sixteen pounds.

55 PARK STREET.

SUBLUXATION OF THE HEAD OF THE RADIUS.

BASED ON THE STUDY OF THIRTY-SEVEN CASES.

BY JACOB GROSSMAN, M.D.,

NEW YORK.

CHIEF OF THE ORTHOPEDIC CLINIC LEBANON HOSPITAL, CHIEF OF THE ORTHOPEDIC CLINIC STUYVESANT POLYCLINIC, INSTRUCTOR OF ORTHOPEDICS NEW YORK POST-GRADUATE MEDICAL SCHOOL.

SUBLUXATION of the head of the radius, also known as "traumatic palsy" of the upper extremity, occurs only in children between the ages of a few months and five years. It is a condition in which a partial dislocation of the head of the radius results from a mild trauma. The trauma is usually applied to the wrists and not to the elbow. The manner in which the condition is produced and the subsequent picture are characteristic. In some instances swinging the child by the wrists, in others dragging the child by taking hold of the wrists is sufficient to produce the subluxation. Immediately thereafter the upper extremity hangs limply at the side and the child refuses to move it. It resembles a flaccid paralysis, hence it is often called "traumatic palsy." There is no paralysis present. The disability is due to pain which may result from movement of the affected extremity. The minimal pain is experienced when all the muscles, especially those below the elbow, are relaxed. It is the relaxation of the muscles which makes this condition simulate a flaccid paralysis.

Many of the cases are overlooked. In a number of instances the patients are brought to us with their forearms encased in splints. In other instances they are brought to us with their shoulders immobilized. On questioning the parents of these patients we learned that they were treated for a sprain of the shoulder or a fracture of one of the bones of the forearm or a sprain of the wrist. In one instance a diagnosis of anterior poliomyelitis was made.

Etiology.—In our series of thirty-seven cases, eleven, or about 29.5 per cent., were in males and twenty-six, or about 70.5 per cent., were in females. The youngest patient was eight months of age and the oldest was six years. There was only one who was six years of age. The majority of them were between two and three years of age. Seventeen were of that age, fourteen of them were below two years of age, one was five, one was six, and four were four years of age.

The manner in which the injury is sustained is characteristic. The child is either raised by the wrists or is dragged along, being gripped by the wrists.

Symptoms.—Immediately thereafter the affected extremity hangs limply at the side. The muscles, especially those below the elbow, become relaxed. The picture resembles that of a flaccid paralysis. Any attempt to move the forearm passively is very painful. Flexion and extension at the elbow cannot be performed. Supination and pronation of the forearm are restricted and painful. Upon forcible extreme supination a clicking sound is heard at which time the head of the radius assumes its normal relationship within the orbicular ligament. Shortly thereafter there is resumption of all the normal functions of the elbow and forearm. The parents are astounded at the sudden change in the picture of the patient.

There are no signs of injury present. Ecchymosis is never present. There may be slight swelling and tenderness in the region of the radio-humeral joint.

Comment.—An *x*-ray examination was made in a number of the cases after the subluxation was reduced. As would be expected it was negative. What occurs is that head of the radius changes its relationship to the orbicular ligament during which time it (the head) slips a little out of its normal position and becomes locked, thereby arresting supination and pronation. Forcible supination overcomes this locking, permitting the head of the radius to slip back and resume its normal movements within the orbicular ligament.

Treatment.—The treatment consists in reduction of the subluxation. It is accomplished by forcible supination of the forearm. No other measure was necessary in our series of cases. As relapses are common the parents are warned to refrain from dragging the children by the wrists or raising or swinging them holding the wrists while doing so.

CASE I.—Baby S., two and a half years of age. Three days before being brought to our clinic the patient was dragged, her mother gripping her right wrist. Shortly thereafter the right forearm hung limply at the side and the child refused to move it. She was taken to the emergency ward of a hospital where a diagnosis of a sprain of the right shoulder was made. The shoulder was immobilized and the child sent home. The patient was brought to the Orthopedic Clinic of Lebanon Hospital three days later.

Examination showed that the right shoulder was immobilized. Upon removal of the dressing the upper extremity fell limply to the side. The child made no attempt to move the arm or forearm. Attempts at passive movements were painful. The muscles below the elbow were relaxed. Upon extreme forcible supination a clicking sound was heard and immediately thereafter movements of the elbow and forearm were painless and free. No further treatment was necessary. When seen one week later, the functions of the elbow and forearm were found to be normal.

CASE II.—Jeanette S., two and a half years of age. A few days before being brought to the Orthopedic Clinic of Lebanon Hospital, the child was swung in the air by her father who gripped her by the wrists. After this incident the child refused to move the left upper extremity. She was taken to a physician who made a diagnosis of sprain of the wrist. Her left wrist was immobilized and she was sent home. She came to us a few days later. Examination showed that the left wrist was immobilized and the forearm was supported in a sling. Upon removal of the bandage and the sling the left upper extremity fell limply to the side, and there was absolute loss of function in it. There was no evidence of an injury. Upon extreme supination of the forearm a clicking sound was heard and immediately thereafter there was resumption of the functions of the upper extremity. No after-treatment was necessary. When seen one week later, there was normal function of the forearm and elbow.

The histories of the other thirty-five cases are similar to the foregoing, and report in detail is unnecessary.

Summary and Conclusions.—1. Subluxation of the head of the radius is a fairly common condition and is often overlooked. It is often diagnosed as sprain of the shoulder and wrist or fracture of the forearm.

2. It occurs only in children, generally between the ages of eight months and three years.

3. The mode of production and the subsequent picture, namely raising or dragging the patient by gripping the wrists and the apparent flaccid paralysis, are characteristic of this condition.

4. It is often called "traumatic palsy" of the upper extremity.

5. Extreme forcible supination is all the treatment required to overcome the subluxation. After care is not necessary.

6. As relapses may occur parents should be warned of the risk of dragging or lifting their children by gripping the wrists.

1182 JACKSON AVENUE.

A METHOD FOR STANDARDIZING THE KNEE JERK TEST AND ITS MEASUREMENT.

BY GUSTAV F. BOEHME, JR., M.D.,

LOS ANGELES, CAL.

FORMERLY CONSULTING NEUROLOGIST, NEW YORK POLICE DEPARTMENT, PSYCHIATRIST, EDUCATIONAL CLINIC, COLLEGE CITY OF NEW YORK; ASSISTANT PHYSICIAN NEW YORK NEUROLOGICAL INSTITUTE; ASSISTANT NEUROLOGIST, VANDERBILT CLINIC; NEUROLOGIST WEST SIDE HOSPITAL, ASSISTANT PHYSICIAN BELLEVUE HOSPITAL, ETC.

To attempt to advance another method for the elicitation of the knee jerk would seem presumptuous, especially as it seems to be the easiest of all tendon jerks to obtain, or at least so all text-books would give us the impression. Yet all of us have been embarrassed at times when we attempted to demonstrate a change in this phenomenon in some patient, to find our results contradictory, or else have been annoyed by the refractory behavior of our patient. Apparently, under nervous strain or excitement, inhibitory impulses modify the condition of this neurotendon reflex, and all the ordinary tricks to elicit the characteristic sign are abortive, or did not avail us. Especially is this true in certain types of medicolegal cases, those following trauma, in which a quite intelligent patient attempts to simulate injury to a leg.

To date the following methods of obtaining the knee jerk have been described:—

1. The patient is seated in a chair and he is instructed to cross one knee over the other, allowing the swinging leg *"to go loose," to relax.* The quadriceps tendon is then struck with the flexed fingers of the examiner, the ulnar border of the hand, or a specially devised hammer (chosen by each examiner according to his own particular predilection). The extensor reflex is obtained when the leg "jerks" forward. Now in a certain type of cases the following occurs:—The patient is tense, is unable "to relax," to let the leg "go loose," and no or a very slight reflex occurs. I have had physicians and nurses say to me, "You can't get my reflex that way," and this is true.

2. Again a second method described is to have the patient seated comfortably, well back on a high chair or table, with both legs "hanging loosely." The tendon is then struck ("and at the same time his attention is diverted," says "Church-Peterson") and the reflex is elicited. Here again the same difficulty occurs—"his attention is diverted"; but this is far from easy in a patient who is being examined by a physician, for under these circumstances the average patient is "all attention," and then again inhibitory impulses change the character of the reflex.

3. By reinforcement—Jendrassik's method. The test is performed as usual, with the difference that an attempt is made by having the patient pull upon his hands, with his eyes closed, to relieve the lower spinal reflex from inhibitions from above by directing these inhibitory impulses into the arms; and this method, in my experience at least, while being of great assistance in overcoming a refrectory reflex, yet fails in a great many instances, for in some individuals the knowledge of the attempt to "make his knee jump" in conjunction with the intensification of his directed attention, adds intensification to the inhibition of the knee jerk. That these patients are frequently of hysteroid types with hypnoid tendencies is undoubtedly the case.

4. In bed-ridden cases, the method commonly employed is to flex and elevate the knee, and place one arm in the popliteal region. The leg is then allowed to drop. The extensor tendon is then percussed and the jerk elicited. The important essential here is the "complete relaxation" of the leg by the patient. Or again the limb to be examined is lightly placed over the other limb and the knee percussed. Here again total relaxation is essential and frequently cannot be obtained.

We note in all these methods the following:—

1. The absence of total relaxation in the examined limb. The actual state of the muscles is entirely dependent upon the patient's ability to control inhibitory or other psychic processes that affect the jerk.

2. An inconstancy of position of the limb examined.

3. A lack of knowledge on the part of the examiner of the state of tension in the extensor quadriceps (although placing the hand on the muscle

group while carrying on the test gives some criterion of this condition).

During the past year I have experimented with a method which I believe overcomes all these difficulties, in all except ankylosed knee or hip joint cases, although the method can be applied even here, always taking into account the anatomical limitations.

The test is performed as follows:—

1. The patient is laid upon his back on a regular examining table.

2. The thigh is flexed upon the abdomen to complete flexion.

3. The knee is flexed upon the thigh to a right angle. This position seems to give just the right amount of tension on the quadriceps to allow of the execution of the test. I have tried lesser and greater angles but with less success.

4. The leg is held with the non-percussing hand preferably grasping the ankle, holding the total limb in the position described.

5. The quadriceps tendon is then carefully palpated to locate the tendon between the lower angle of the patella and the tibial tubercle. It will present a moderate degree of tension.

6. The area described is then percussed with the percussion hammer, when an extension movement of the leg on the thigh occurs. The spontaneousness of the reflex, the intensity, etc., can then well be measured by the hand holding the leg in position.

This measure gives us a method of testing the knee jerk with constant factors:—(1) As to position of the limb. (2) As to tension on the quadriceps. (3) As to mental inhibition.

Having all these factors constant a method measuring the difference in the two knee jerks (if there is any) has been employed. Further reports on the actual measurements will be forthcoming in a paper to follow.

The ordinary blood-pressure cuff is carefully bound about the middle of the thigh, the inflated bag crossing the extensor muscle. The instrument is then inflated to 100 mm. (an arbitrary figure, but one with which I have obtained best results). The jerk is then elicited as described and the amount of oscillation of the needle or mercury is read. Normally this seems to be between 7 and 12 mm. of Hg.

I do not know of any method that will give as constant results as the one described. I have searched for a description of a similar method, and not being able to find one, I offer it to the profession.

ROOM 234, CONSOLIDATED REALTY BUILDING.

Amenorrhea and Marriage.—Siredey answers the question "Should a young girl with amenorrhea marry?" It is embarrassing for the physician to assume the responsibility in some of these cases. He must always carefully exclude error of sex and hematometra as well as infantilism. In this connection he must consider from all angles the question of endocrine motivation which is very common; during the war there were many of these cases traceable to shock. Intensive opotherapy should be pushed in doubtful cases, both for diagnosis and treatment. To put the case in a nutshell, if the examination reveals perfect sexual development and normal organs of copulation, it is best to sanction marriage.—*La Presse Médicale.*

DRUGS AND THEIR ACTIVE PRINCIPLES IN RELATION TO THE TREATMENT OF DISEASE.

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

NOTHING has impressed me more lately than the learned discussions which have been carried on by prominent English practitioners in their treatment of malaria. Many of them dwelt solely, or almost entirely, upon the use of quinine in different ways in its treatment. A limited few, and only after the debate was near its end, dwelt upon the importance and advisability of giving the united alkaloids of cinchona bark to obtain the best effects of treatment in, at least, some forms of malaria.

To me it has been a great regret that no mention was made of the remarkable efficacy of Huxham's tincture of bark, and especially because, over one hundred years ago, this prominent physician of England emphasized its great therapeutic value and rightly so. When quinine and even the combined alkaloids fail to do good work in curing malaria, the compound tincture of bark will, I believe, do the trick and bring to a rapid end all evidences of malaria, so far as symptoms are concerned, and also, at times, any evidences of it that can proceed from laboratory research.

This statement leads me to question closely the value of some refinements in medication, which the modern physician is too apt to abide by in the treatment of not a few diseases; hence, in my judgment, a great and serious loss to useful medication.

In days gone by opium in some form was frequently used to abolish pain and to lessen, or bring to an end, inflammatory disease. Anyone who is familiar with Alonzo Clark's treatment of acute peritonitis with large and frequent doses of opium, must see in this doing much that has value, even to-day, and when operations galore are the password of most physicians. Alas, the pity of it!

Does morphine take the place effectively of opium in this and other acute inflammations? Surely it does not. It is more convenient, and at times, to be sure, the ready hypodermic syringe may be seemingly used with advantage. But I question the advantage of putting aside the use of extract of opium or laudanum except rarely, and then only to tide over a most urgent occurrence.

If pain is at all continuous; if it means, as often it does, disease of some duration, then opium is still the master key in disease. In their foolish and wrong legislation the controllers among us have so limited and obstructed the physician's use of narcotics that to-day not a few of the older as well as the younger physicians have simply abandoned the use of this most beneficent drug.

Again, it would seem from some late experiences among men of tried value in our profession that to prescribe narcotics even with wisdom and rectitude is fraught with danger of prosecution or even imprisonment. Only lately the London *Lancet*, in an editorial on drugs and their true

principles, showed unerringly how misguided are the physicians, clinically, who abandon the galenical preparations of former days for the powerful alkaloids, which to-day have, as it were, the front seat in the practice of medicine.

Of course we occasionally see a prescription for nux vomica, or the tincture thereof, where a tonic is required. But how much oftener do we find the ominpresent strychnine in all prescriptions! Are they the same and do they fill the same indications? I am confident they do not. There is a something in the crude plant, or in the elements of it which are extracted with alcohol that is not measured up to with the alkaloid alone. A late writer asks very pertinently whether we should expect to obtain the same good effects from a few grains of caffeine in hot water that we should certainly get from a well-made infusion of tea.

What are the modern vitamines and where are they always found?

We do not know, but we do know that polished rice when eaten to the exclusion of other food, will give beriberi. When eaten in its natural form it is one of the very best vegetables and serves, by itself almost, to give energy, activity, and working brains to millions of Japanese.

In the so-called inert matters those indeed that are not extracted by any chemical means, we have some form of energy which may be swallowed by humans, often to their very great benefit.

My subject is a big one and I shall not attempt to handle it at any length. But I beg that a halt may be called to the too general use of the alkaloids, at the expense of many drugs and combinations, which our forebears told us were of very great service in the relief of human ills.

129 East Thirty-fifth Street.

MENINGITIS SEROSA.

By ROBERT A. KILDUFFE, A.M., M.D.,

PITTSBURGH, PA.

DIRECTOR OF LABORATORIES, PITTSBURGH HOSPITAL, DIRECTOR OF LABORATORIES, MCKEESPORT HOSPITAL, BACTERIOLOGIST TO THE CITY OF MCKEESPORT, SEROLOGIST, PROVIDENCE HOSPITAL, FORMERLY MAJOR M. C., U. S. A

CONCERNING this condition — first described and named by Quincke—some confusion exists, both as to its occurrence and as to what conditions shall be so designated. Comparatively little is to be found regarding it in the literature, in all probability not because it is so infrequent, but because, perhaps, it is not recognized or reported as such. It is possible that, were it looked for, the condition would prove far from infrequent. Some confusion appears to exist, also, as to the terminology, the terms "toxic meningitis" and "sympathetic meningitis being applied to it; although, if we define it to mean simply a state of irritation without a definite inflammatory reaction, the term meningitis serosa is probably to be preferred.

Looked upon in this light, meningitis serosa is a condition characterized by pronounced and evident symptoms of meningeal irritation, in which the ependyma is stimulated to over-activity with resultant marked increase in the amount of cerebrospinal fluid secreted, which, however, upon laboratory examination, shows little or no change from the normal. The condition is, apparently, due to the action of a toxin or toxins the source of which is not always evident. It has been noted as a concomitant of alcoholism and as accompanying gastroenteritis in infants. In this connection, one is tempted to speculate upon the possibility and frequency of its occurrence in cases of "convulsions" in children apparently following dietetic indiscretions, and to wonder to what extent it may follow toxemias arising in the intestinal tract.

The case herewith reported occurred during the writer's service as Chief of the Pathological Department of Camp Hospital No. 72, A. E. F., and is of some interest as illustrating a fairly typical picture even though, owing to lack of laboratory facilities, the laboratory examinations were not exhaustive.

Case Report.—Corporal L. D. S. was admitted to the hospital without definite history other than that on the previous evening, in a French hotel, he had eaten a dinner of somewhat mammoth proportions. There was also an indefinite history of constipation extending over a period of some few days previous to the present illness. The following morning he reported for duty but was relieved on account of headache and general languor. He went to his quarters where, he remembers, the headache became very intense. His next recollection is of vomiting profusely—the emesis apparently being of a projectile character—and he has a somewhat hazy remembrance of being helped into his clothes.

None of this history was obtained at the time of entrance, the patient being in a semiconscious condition, extremely irritable when handled, constantly trying to lie on his side, and unintelligible in speech, but indicating by gestures severe frontal headache. Practically no information could be obtained from him.

The physical examination was negative except for the presence of a doubtful Kernig sign. There was no Babinski. A lumbar puncture was done, a large amount of spinal fluid under well-marked pressure being obtained. A striking feature of the case was the immediate and spectacular relief of the symptoms following the puncture, the patient becoming oriented almost immediately upon the withdrawal of the needle and being able to give a history and to complain of the headache.

The examination of the spinal fluid gave results as follows: Quantity: 50 c.c. Appearance: clear and limpid; no macroscopic blood, pus, nor fibrin. Cell Count: 250 cells per cu. mm. Culture: negative for meningococci or other organisms. Microscopic: bacteria absent. Numerous polymorphonuclear leukocytes; moderate numbers of small mononuclear lymphocytes. Globulin: Ross-Jones test: faint haze. Pandy's test: faint haze.

Owing to lack of laboratory facilities it was not possible to do a Wassermann test or colloidal gold reaction.

The day following the puncture the symptoms had practically disappeared and the patient complained only of marked constipation. Forty-eight hours afterwards he was perfectly well.

In the interpretation of this case several possibilities are to be considered and eliminated: A *Meningococcic meningitis:* Negatived by the character of the fluid, the negative cultures and microscopic examination, and the subsequent course of the case. B. *Tuberculous meningitis:* Negatived by the laboratory findings and the favorable termination of the case within forty-eight hours. C. *Poliomyelitis:* Negatived by the course of events and the laboratory findings. D. *Cerebral tumor:* Negatived by the history, physical findings, laboratory findings, and the immediate clearing of the symptoms. E. *Pyogenic meningitis* (organisms other than the meningococcus): Negatived by the laboratory findings and the clinical course of events. F. *Meningitis serosa:* A condition occurring more

frequently in adults, characterized by symptoms of meningeal pressure and irritation, apparently non-inflammatory in character, fairly acute in onset with varying degrees of increased pressure in the cerebrospinal fluid, accompanied by negative laboratory findings — conditions fulfilled in this case. There is only one minor discrepancy: the cell count. Recalling, however, the immediate response to the injection of serum by an outpouring of leukocytes—a condition frequently noted and referred to—it seems justifiable to look upon the increased numbers found as simply a response to a pronounced toxemic irritation which, if we are to consider the history, would seem to have arisen in the intestinal canal.

THE PITTSBURGH HOSPITAL.

ACUTE VERONAL POISONING SIMULATING LETHARGIC ENCEPHALITIS.

BY ERNEST MACLEOD,

CENTRALIA, WASH.

THE following case presents some points of interest which seem to warrant a report:

Male, æt. 44, suffering from insomnia for which he was using bromidia—called for examination of the lungs on April 6, 1920. This examination showed chronic bronchitis and healed tuberculous lesions; breath sounds absent at the base of both lungs posteriorly. Liver dullness increased below. The man had been constipated for years; mental torpor, probably from long use of bromides. On April 9 his wife phoned he had been asleep since April 7 and could not be aroused.

Examination showed profound unconsciousness—pupils slightly dilated, no reaction to light, no conjunctival reflex, Babinski, knee jerk, and ankle clonus absent. Resp. 20, P. 84, T. 98°. Jaw rigid. No bowel movement nor urine passed since going to sleep the night of the 7th. The pain of catheterizing a strictured urethra aroused him sufficiently to swear. Only 6 oz. of urine was obtained. Feeding per rectum was instituted.

There was low muttering delirium. Profuse salivation night and day, the saliva dribbling from the mouth saturating the pillows. He remained in this condition until 6 P. M. April 14, when he could be aroused momentarily. April 16 he was completely conscious and said he had taken 14 5-grain barbital (veronal) tablets in divided doses over a period of 36 hours. The temperature was normal throughout; the pulse varied from 80 to 100; the respirations were 20 to 44. Urine examination negative.

This prolonged sleep from veronal suggested its use in status epilepticus with happy results from 30 grains in divided doses. In probably other mental conditions as morphinomania, etc., a week's sleep would eliminate the pain and suffering from withdrawal of the drug.

ZIMMER BUILDING.

Obsolete Warships as Laboratories for the Study of Foot and Mouth Disease.—The British Admiralty has assigned to the Ministry of Agriculture obsolete warships to be used as laboratories for the investigation of foot and mouth disease. The warships proceed to sea, and the research work is carried on in the open ocean. Perfect safety against the dissemination of infection is thus secured. The virus of the disease is supposed to be ultramicroscopic; there is also a possibility that the infection is air-borne. The elucidation of the problem constituted by the cause of foot and mouth disease is comparable with that of cancer—elusive, difficult, and affording but little prospect of a definite solution.—*The Medical Press and Circular.*

Medicolegal Notes.

Competency of Expert Medical Witness, How Shown.—On a murder trial, the coroner, himself a physician, had described, as a witness, the wound on the deceased's body, and the bones broken by the blow. He stated, without objection, that the wound was produced by a blunt instrument, and had been inflicted for some time, probably a number of hours, before death, and had given his reasons therefor, which were the technical reasons of a physician and surgeon. He described the condition of the brain with relation to the external matter collected therein, and its effect. After he had thus testified, he was asked whether he found any other evidence that would lead him to believe the injury causing the death had been inflicted for some length of time, to which he replied: "There was not so very much blood in the body. The body had bled a good deal; and it must have been bleeding from a small place, because that was the only place it had to bleed from." On appeal, the defendant complained of the admission of this answer. It was held that the question scarcely called for the expression of an opinion; but, even assuming that the witness' belief was merely an impression formed from the condition in which he found the body, there was, nevertheless, sufficient prior testimony from this witness to admit the answer as the opinion of an expert. Moreover, the witness was subjected to a searching cross examination by the defendant's counsel on all technical matters pertaining to the injury and its probable effect, and, had the former not been a physician of some ability, it would have been readily perceived as a result of such examination. While the competency of the witness should first appear before he is permitted to express an opinion, and the general practice is to interrogate him on this subject before his testimony is received, yet when the opposing party knows that a witness is about to give testimony which should come from an expert, and specifically objects on that ground, he should exercise his right to cross examine as to the qualifications of the witness. If he does not do so he cannot be heard to complain. The defendant did not offer to cross examine the witness on this subject.—Commonwealth v. Johnson, Pennsylvania Supreme Court, 109 Atl. 218.

Charitable Hospital Not Liable for Injuries to Pay Patient.—In an action for personal injuries sustained by the plaintiff from having received from a nurse a massage with carbolic acid instead of alcohol at the defendant hospital, the Missouri Supreme Court holds that a corporate hospital, organized to nurse the sick and to exercise care for the poor and aged by deaconesses, and to found and support a deaconess home, where nurses should be trained, and which issued no stock and paid its members no profits, is a charitable organization. The charitable character of the hospital was not lost because it received pay patients, from whom the greater part of its income was derived. Being a charitable hospital, the defendant was not liable for the plaintiff's injuries, the doctrine of respondeat superior not applying in such cases. The fact that the plaintiff was not a charity patient, and that she paid for all the services rendered and for supplies and medicines was held immaterial, and to give the plaintiff no greater right to divert a trust fund than if she had been a charity patient.—Nicholas v. Evangelical Deaconess Home and Hospital, Missouri Supreme Court, 219 S. W. 643.

Award Without Requiring Examination by Physician Held Erroneous.—In a Workmen's Compensation proceeding, whose claim was made and compensation awarded for the loss of 25 per cent. of the vision of both eyes, it was held on appeal that the commission erred in not requiring the claimant to submit to an examination by an eye specialist. In the first place, the employer is entitled, under the act, to obtain from a man of skill an opinion as to the workman's condition for the purpose of determining whether or not he will settle the claim without litigation, and in the second place, if a settlement cannot be reached he is entitled to this information so that he may present it to the arbitrator or industrial commission for its consideration in determining the amount of compensation to which the employee is entitled.—Hafer Washed Coal Co. v. Industrial Commission, Illinois Supreme Court, 127 N. E. 752.

THE X-RAY TREATMENT OF TUMORS OF THE HYPOPHYSIS.

THE radiographic exploration of the sella turcica, the study of its shape and size, the presence or disappearance of the clinoid apophyses furnish for the diagnosis of the presence, size, and extension of a tumor of the hypophysis elements of appreciation of the highest order. Other than those cases in which an antisyphilitic treatment is indicated, tumors of the hypophysis come under surgical treatment or treatment by radiotherapy. Hypophysectomy must of necessity remain incomplete since the hypophysis is an organ indispensable to the organism. It is a blind operation at the best and has a heavy mortality; and even when it is successful, the results are so often nil, insufficient or temporary that many excellent surgeons prefer simply a decompressive trepanation.

Radiotherapy is not merely inoffensive, but has given unquestionable proofs of great efficacy and durability of results. Béclère of Paris has obtained by this complete disappearance of headache, vertigo, nausea and vomiting, in other words of all the symptoms of intracranial hypertension. The amelioration of the visual disturbances which is all the more marked the earlier radiotherapy is begun, before irremediable atrophy of the optic nerves has taken place, is made evident by an eccentric increase of the narrowed visual field, by the recovery of the ability to read and write and a return to the possibility of walking alone in the streets. Of course the acquired skeletal lesions do not retrogress, but they no longer increase.

On the other hand, in a mixed case of exaggerated growth with obesity and genital infantilism in a girl of sixteen, whose hypophysary tumor was made evident by an enlarged sella turcica with symptoms of intracranial pressure and serious ocular disturbances, Béclère was able to reduce the adiposity, while menstruation returned accompanied by development of the breasts and growth of the pubic and axillary hair. In other words, the ovarian functions and secondary sexual characters returned. In patients who have been followed after treatment with the *x*-rays, the therapeutic results obtained have persisted two to six years and, in one case, eleven years.

Radiotherapy is imperiously indicated when symptoms of a mechanical order appear, such as intracranial hypertension or compression of the chiasma of the optic nerves, when the former persists and the latter progresses. This also applies to trophic symptoms indicating hyperfunctions of the hypophysis, namely hyperosteogenesis of the giant or acromegalic type.

On the other hand, treatment should be stopped when the amelioration of the ocular disturbances has ceased for several months and when the hyperosteogenesis has reached its point of arrest. Radiotherapy is even contraindicated in gigantism and acromegaly, at the phase of decline when the hyperplastic lesions of the pituitary cells take the place of retrogressive destructive lesions and when the glandular hyperfunction is succeeded by functional insufficiency, which may be incompatible with life. In principle, radiotherapy is contraindicated in the simple types of adiposogenital dystrophy, because this syndrome is attributed to a hyperfunction of the posterior lobe of the hypophysis. But in reality this syndrome, which is dependent upon various and multiple lesions, may be the indirect consequence of a pituitary or juxtapituitary tumor, causing compression of the posterior lobe, occlusion of the infundibular canal, or ventricular hydropsy, which is revealed by symptoms of intracranial pressure and ocular disturbances. Consequently it is these symptoms that indicate resort to radiotherapy.

Briefly, the *x*-ray treatment will bring about retrogression of intracranial hypertension and visual disturbances resulting from tumors of the hypophysis, and being devoid of danger is a therapeutic method to be seriously taken into consideration.

THE PROBLEM OF MALARIA.

ALTHOUGH one hears less of malaria than of some other widespread and destructive diseases, it is a question whether on the whole malaria does not do more injury to health than any disease. In the first place, there is no disease more widely disseminated than malaria and no disease, given favoring conditions, which will spread more rapidly. In these days it is not regarded as an especially destructive disease, but if history is read aright it was largely responsible for the fall of ancient Greece and its civilization. Malaria is an active disease in many parts of this country and taxes the abilities and resources of the members of the Public Health Service to hold it at bay.

Of course, so far as malaria is concerned, preventive measures are the only sure means of ridding an area of the malady. However, while destruction of the breeding places of the anopheline mosquito is the only certain method of extirpating the disease root and branch, such measures are not always feasible and in any event take time. Therefore curative, or rather remedial and prophylactic measures still hold sway. Of all the therapeutic and prophylactic remedies for malaria none has approached in reputation that of quin-

ine. For years it has been the sheet anchor of treatment and prophylaxis, and the faith reposed in its efficacy has been almost touching. Now and then cold water has been thrown upon its claims, but, as a rule, it has retained its reputation in a remarkable manner.

During the war a good deal of experience was gained in the prophylaxis and treatment of malaria. Some of the military operations were undertaken in notoriously malarious districts, notably in Macedonia, a part of that ancient Greece of which mention has been made, in Egypt and Palestine, and elsewhere. From the experience thus gathered views as to the virtues of quinine in the treatment of malaria have varied considerably, but speaking generally it may be said that quinine has fallen somewhat from its high estate.

In the *Medical Press and Circular* of November 3, 1920, Dr. J. C. McWalter has an article concerning the prophylactic treatment of malaria, dealing chiefly with the effects of quinine as witnessed by him as specialist sanitary officer, R. A. M. C. According to him, the net result of the collective experience of the officers of the R. A. M. C. is that, despite the use of quinine, in fact and practice 90 per cent. of the men who were in Salonica, especially those in the Lake Doiran district, got malaria, and but few, probably not more than 20 per cent, of those who served in Egypt or Palestine escaped. McWalter regards the prevention or cure of malaria and dysentery as not only the most urgent question of tropical preventive medicine, but one on which depends the future history of the British Eastern empire. He further points out that investigation or research on the subject is not solely a matter for the laboratory, the question must be treated clinically on a large scale. He does not believe that quinine is quite useless or inert, for at a certain very early stage in the onset of an attack, it prevents its development. It has probably some antiperiodic effect, but it cannot be relied on as a prophylactic. It does not, he says, even prevent recurrence of attacks when there is no fresh infection. It seems in many instances to prolong the interval between attacks, but this is so dependent on the weather and other causes that it is hard to eliminate everything but the action of the drug. McWalter records his opinion that in spite of all that has been written and said about malaria and quinine, one finds that the question needs to be studied afresh as an actual problem affecting great armies.

Another point in the dissemination of malaria where McWalter diverges from the beaten path is with regard to the mosquitos which propagate malaria and when they do their evil work. He draws attention to the fact that the anophele is not the only species of mosquito which transmits malaria; some species of culex also give it. Also, it is incorrect to say that malarial mosquitos bite only in the dark or at dew-fall; that is the worst time, but they bite all day. He found, moreover, that the quotidian, tertian, and quartan types of malaria are largely traditional.

THE SYMPTOMATOLOGY AND COMPLICATIONS OF SPERMATIC CYSTS.

CYSTS of the epididymis are by far the most frequently met with in practice of the spermatic cysts, and all develop slowly and painlessly so that their onset is overlooked. It is only by mere chance that the patient makes the discovery of a small nodule, the size of a pea or filbert in the epididymis which gives rise to no functional disturbance or pain. This small nodule progresses with extreme slowness and ordinarily requires from two to five years or even more to attain the size of a pigeon's egg. When fully developed, the cyst may cause some discomfort in walking on account of its weight and size, but it is painless. If the patient is examined at this time, inspection will show that one side of the scrotum is—as in hydrocele—the seat of an evenly rounded tumefaction which is more or less pronounced. Usually there is no appreciable development of the subcutaneous veins of the scrotum and the skin covering the tumefaction is always normal. Percussion gives absolute dullness, while palpation shows that the tumor is a regularly rounded oval body, elastic or fluctuating. The scrotal skin is freely movable over the tumor, while at the lower pole of the latter the testicle can be readily made out.

The local lesion formed by the cyst and testicle frequently assumes the characteristic shape and seems to be a single mass, but if the cyst is drawn upward and immobilized with fingers of one hand while the testicle is held with the fingers of the other hand, this organ will usually be found to be independent of the tumor and can be moved transversely over it. The epididymis is less easy to recognize as the cyst develops in its substance or in its immediate proximity. However, if the testicle is firmly held and drawn slightly downward so as to put the cord on the stretch, the tail and body of the epididymis may sometimes be made out. The head is always indistinguishable from the cyst. The vas deferens and most of the elements of the cord are usually easily recognized over the posterior aspect of the pathological production. The cyst is not translucent, or if partially so it is never as perfect as in hydroceles. Rectal examination reveals a normal prostate and seminal vesicles.

The prognosis of these cysts is good, and the disturbances of spermatogenesis to which they sometimes give rise are of little moment.

Complications are likewise rather the exception. The cyst has been known to rupture into the vaginalis or cellular tissue of the cord following traumatisms, while an instance of torsion of the pedicle has been recorded where the cyst was attached to the head of the epididymis by vessels of unusual length. The contents of the cyst may be bloody but this transformation of the fluid is usually the result of trauma and is very rarely due to the classical mechanism of spontaneous hematocele. Inflammation of the cyst is somewhat more frequent, but it is discrete and subsides in a few days, leaving a little induration in the walls of the cyst. Very

large spermatic cysts have been known to cause varicocele or marked atrophy of the testicle; or the cyst may be complicated by hydrocele, in which case the latter completely conceals the cystic process, thus making its diagnosis difficult. It is undoubtedly due to a direct action of the cyst which irritates the serosa like a foreign body. Some years since, Aubert advanced the theory that rupture of small spermatic cysts into the vaginalis was a frequent cause of hydrocele because his cystological examinations of the fluid of this process revealed the presence of spermatozoa.

LO, THE POOR INTERNE!

THE hospital interne is generally conceded to have a hard lot. Responsible to attendings, to superintendents, to patients, to relatives; often (perhaps deservedly) abused by all; working, if he be at all conscientious, many hours a day; with blame for mistakes and often with scant praise for work well done; one may well wonder that the breed persists. Many months of the interne's career must be spent in doing what he himself is prone to call "scut work"—*i.e.* uranalyses, blood counts, and all the rest of clinical pathology; or dressing the uninteresting surgical cases; giving anesthetics; and, all too often, "riding the bus." In these days of residents and assistant residents, many of the men just graduated from medical schools look askance at the hospitals which have installed the "resident system" and turn their attention to hospitals which are perhaps less desirable, on the ground that they can there "get more to do." This point of view is particularly popular with men seeking surgical internships. It is the fashion with even the least experienced to scorn the lowly hemorrhoid and to long for a chance to "do a gall-bladder" or a hysterectomy.

What the interne wants (of course leaving the lazy ones out of consideration) is "plenty to do." He is tired of being taught, tired of standing round while other men prescribe, tired of pulling out stitches someone else has put in. He wants so much first-hand experience in the hospital that when he is turned loose upon the sick public, he will have confidence and ability enough to "get away with it."

Some hospitals cling to the idea that in the ambulance service the interne gets valuable first-hand experience in meeting emergencies. Requiring trained doctors to spend many hours a week "riding the bus" is something which more and more hospitals are coming to regard as foolish and unprofitable. For the interne who clings to the tail-end of an ambulance is practically never called upon to use his store of medical knowledge. A little common sense, presence of mind, and the ability to tell whether or not a case really requires hospital care are the only qualifications which rank the "ambulance surgeon" higher than a footman. Many progressive hospitals are clearly demonstrating that drivers or orderlies with a working knowledge of first aid can do creditable and satisfactory work as ambulance surgeons. Thus the interne is kept in the accident and admitting rooms, where he spends more time on his cases than he does on street traffic. Only a chance emergency obstetrical case would require the presence of a doctor; and this could be very well provided for without such unwarrantable loss of time as on the ordinary run of ambulance cases. When an interne in any of our accredited hospitals, with first-class attending physicians and surgeons, begins to complain of having too much laboratory work to do, or of having too little responsibility, the voice of his complaint may well merit little consideration. Given honesty and industry on his part, his interneship will be as profitable as he could wish. But when he begins to complain of being obliged to waste his time and energies on the city streets, hospital authorities may well listen to him, or else keep silent when they find themselves equipped with second-rate interne staffs.

LINITIS PLASTICA AND ITS CLINICAL SYNDROMES.

PLASTIC linitis is characterized by a general infiltration of woody hardness in the gastric walls. The wall is greatly thickened, forming a rigid carapace and reducing the capacity of the stomach. Its thickness is one or two inches, and it has even attained three or four in some instances. On the other hand, the cavity of the stomach is so reduced that it can hold only a few spoonfuls of liquid. Finally the shell formed by the gastric wall is so rigid that it can neither distend for receiving the slightest amount of solid food nor contract for expelling solid contents in the intestine. A stomach of very small dimensions, with very thick, rigid walls, is therefore characteristic of gastric linitis.

At the present time this process is classified among neoplasms, especially since characteristic cancer cells have been found to exist in the morbid structure. This process is a peculiar type of cancer that does not involve the surface epithelium, but cleaves the subjacent structures by means of a sclerous tissue, which surrounds the muscular fibers. There may, perhaps, be other sclerous processes of the same type, due to tuberculosis or syphilis, but it appears that malignancy is usually the course.

Gastric linitis may be limited to the body of the stomach or may involve the body and either the cardia or pylorus as well. If the linitis is localized to the body of the stomach, without participation of either the cardiac or the pyloric orifice, one will find a microgastria with rigidity and thickening of the stomach walls. If the syndrome of dysphagia and regurgitation exists and the case is one of pseudostenosis at the cardiac end of the esophagus, the diagnosis can readily be made by giving a bismuth test meal, which will be found to fill the gastric cavity and esophagus. If the linitis has invaded the cardia as well, the rigidity of this orifice will be made evident by a true cardiac stenosis and will symptomatically overshadow the insuffiient capacity of the stomach. Finally, if the morbid process involves the pylorus, there will be rigidity of the pyloric orifice, which will counteract any tendency to stenosis.

Certain Symptomatological Aspects of Pulmonary Cavities in Tuberculosis.

Among the anatomicoclinical phases of pulmonary tuberculosis, the cavitary phase is the one that best retains its clinical individuality. In some patients who have reached the cavitary stage the general health remains good, and many do not present any of the classical signs of cavity on auscultation, the pulmonary lesion being detected by radiography. In the first place there are silent cavities giving rise to no clinical signs, in which auscultation is almost normal so far as they are concerned. At the most does one find some incomplete percussion dullness and respiratory changes in these subjects. But there are cases of pulmonary cavitation with most deceptive symptoms and to these we would particularly call attention. There are cavities giving rise to evidences of dryness in which auscultation reveals only some crackling, an increase of the vibrations, and respiratory roughness. There are cavities giving rise to moist signs, with subcrepitant râles, moist crackling sounds, and a blowing expiration. In these circumstances there are certainly no characteristic signs of a pulmonary cavity. The subcrepitant râles and dry crackling do not figure in the classical picture of pulmonary cavities, and in reality they usually merely indicate the condition of the pulmonary parenchyma lying between the cavity and the examiner's ear. From these facts some interesting conclusions can be drawn. The first is that the Roentgen rays alone are able to reveal with certainty all pulmonary cavities, and Masselot of Tunis has shown that the frequency of unsuspected pulmonary cavities should lead to better prognoses in many cases. Once again is confirmed the general principle that the functional condition rules over the physical condition, and that in pulmonary tuberculosis in particular, the degree of tuberculous impregnation and the state of organic resistance of the subject are prognostic factors of far greater importance than the physical state of the patient. A tuberculous patient is not always to be condemned to death simply because he presents pulmonary cavities, but the condition is much more grave when the subject is hectic, no matter what may be the anatomical degree of the lesions present.

The Hyperkinetic Form of Epidemic Encephalitis.

Since it is Economo of Trieste who is credited with having published the first account of encephalitis lethargica, it should be of interest to read his experience with the hyperkinetic form, which was practically absent in the outbreak of 1916. His article appears in the *Wiener klinische Wochenschrift* for April 15 and 22, 1920, xxxiii, 16-17, and the conclusions are as follows, with especial reference to the nature of the virus and its relationship to grippe. The hypothetical virus of encephalitis may also be that of influenza, and this view explains the epidemiology of the disease, but in the clinic the bacteriology and pathology show wide discrepancies. The compromise view would be that the relationship of influenza to encephalitis agrees with that between lues and progressive paresis; were it not for the fact that in the majority of cases of encephalitis there is no history of grippe. One might imagine further that the diplostreptococcus of Wiesner, believed by the author to be the cause of encephalitis, is able to cause influenza; as a matter of fact it was frequently encountered during the grippe. But the most plausible view is that encephalitis has its own special cause as stated above, and that coincidentally it must be associated with the unknown causal agency of influenza, either in a true symbiosis or a more casual association. The separate prevalence of each affection without the other could thus be explained as well as the coincidences and sequences and hybrid cases of the two affections. Economo does not believe in the existence of a grippe located in the brain. Clinically the myoclonic form means that the cause of encephalitis has attacked the spine, which it did not do at the outset, causing a poliomyelitis.

Hyperparotidia.

Dalche, writing in *La Presse Médicale* for November 3, 1920, xxviii, 80, makes an attempt to increase the number of diseases of internal secretion by including certain affections of the parotids, some of which at least belong under Mikulicz's syndrome. This is not, of course, the first attempt in this direction. An hypertrophy, or as one might say, a condition not unlike exophthalmic goiter in the thyroid, appears to attack women by preference, and the author narrates two cases of this sort. One woman who had reached the menopause had attacks of pain in the parotid regions—one or two a month. First one then the other of the glands was complained of. There was some sensitiveness on pressure. No enlargement was specified, but the author excluded mumps. In the other case there was swelling of the glands which included both parotids and submaxillaries. In this second case salivation was a feature. Mumps was excluded as in the first case. Neither woman presented any disturbance of the lacrymal glands. The elevated blood pressure in the women could hardly be regarded as due to increased internal secretion of the salivary glands, for both subjects were at the menopause when hypertension would be expected. The lacrymal glands have been known to swell during the menses. The simplest explanation is that the ovary was in some way responsible for the glandular manifestations; just as we see the thyroid swell during menstruation and pregnancy, the pituitary undergo alterations during gestation, and other similar phenomena of ovarian suppression. The close connection in man between the salivary glands and gonads is also suggested. The glands in question do not often figure in pluriglandular syndromes, but a careful study of Mikulicz's syndrome might serve to reveal certain overlooked cases.

News of the Week.

Tuberculosis Increases Alarmingly in Vienna.—The American Red Cross in Vienna reports an increase of 200 per cent. in the number of tuberculosis cases over that of last year, when 16,000 patients were treated in the dispensaries of Vienna and 12,000 were visited in their homes. This year there have been 23,000 cases of tuberculosis under treat-

ment in the Red Cross institutions, while 37,000 patients have received American relief in their homes. The so-called advanced cases number 13,000, as against 10,000 last year. Vienna hospitals have just received American gifts valued at 50,000 Austrian crowns, 50 per cent. of them being in hospital supplies and medicines.

Physicians Admitted to Turkey.—A dispatch from Constantinople reports that the Turkish Nationalists, who for a time past have denied the Near East Relief permission to carry on their work in the interior parts of the country or make an investigation of conditions, have finally agreed to permit physicians to proceed into the interior. Relief workers will not benefit by this favor which had been extended to physicians only.

Teaching Trades to Ex-Service Consumptives.—The *Army and Navy Zone,* in a recent issue, describes the way in which many former Service men are benefited by the helpful charitable work of the New York Tuberculosis Association and the National Tuberculosis Association. In a model workshop in Long Island City, N. Y., convalescent tuberculosis patients are taught the trades of watch and jewelry repairing and cabinet making. These trades are deemed more desirable because not injurious to the lungs. The work is carried on under the best sanitary conditions, a rest room is provided, and meals are served at cost. Schools for pre-vocational training are conducted by the association at the sanatoria of Loomis, Otisville, and Gaylord Farm, and as soon as the patient's physical condition permits he is transferred to the workshop in New York City, or, if an ex-service man, to Long Island City.

The Cause of Infantile Paralysis.—The Minnesota University Farm School, in cooperation with certain medical authorities, has been carrying on an investigation which seems to have demonstrated conclusively that the larva of the bottle-fly is responsible for hog paralysis and limberneck in poultry. A statement has also been issued expressing the belief that infantile paralysis is traceable to the larva of the green bottle-fly. On the basis of the information gained by these investigations, the University officials have sent out a bulletin to Minnesota farmers urging them to protect their live stock and poultry and possibly human health, by burning or burying deeply all carrion. The results of this work are cited as an additional argument for farm and home sanitation.

To Curb Sale of Narcotics.—The Registration Department of the State of Massachusetts has drawn up a bill to be submitted to the Legislature which aims to curb the sale of narcotics disguised as medicine by grocery and other stores unless they take out a State license. Another recommendation for legislation provides for the appointment of investigators and prosecuting officers for the protection of the public against the illegal practice of medicine, pharmacy, dentistry, optometry, chiropody, veterinary medicine, and embalming.

Red Cross Wins Drive in Manhattan.—The Red Cross drive for 400,000 members in Manhattan has closed, there being sufficient pledges to indicate that the 400,000 mark set for the city has been passed.

Addition to Broad Street Hospital.—Plans have been filed with the Manhattan Bureau of Buildings for building an addition and making necessary alterations to the Broad Street Hospital, New York. The new building will be located at 123 and 125 Broad Street, and will cost approximately $300,000.

Few New York Doctors Renew Liquor Permits.—According to an announcement made by Charles R. O'Connor, Federal Prohibition Director, applications for renewal of permits to prescribe liquor have been filed by only one-sixth the physicians of the State, New York City included, who held 1920 permits. There is a shrinkage not only in the renewals to prescribe and manufacture liquor, but also in the number of permits for druggists and perfumers. Of 6,131 physicians who had permits this year, only 985 have obtained renewals.

Rent Free Houses for Worthy Blind.—Patrick H. Vaughn of Harrisburg, Pa., known as the "model landlord," because he refused to raise the rents of his numerous properties during the war, in his will recently probated, set aside ten of his houses in which the families of worthy blind may be permitted to live rent free. His will also provides a home for aged women and for other local charities.

Jewish Memorial Hospital.—It is planned to hold the dedication exercises of the Jewish Memorial Hospital, New York, which is to be erected as a memorial to Jewish soldiers who lost their lives in the war, upon a site which has been selected in the upper section of Washington Heights, some time this month. There are already several buildings on the site suitable for hospital purposes. The total estimated cost of the building is $500,000. The institution will be non-sectarian and the surgical department will be at the service of all registered physicians.

Thieves Use Ruse to Get Doctors' Clothing.—A scheme is being tried in New York City whereby, in one instance at least, a doctor lost no inconsiderable part of his winter wardrobe. The *modus operandi* is something as follows: The telephone bell rings and someone inquires whether the doctor is in and when he will be home. If told he is gone for some time, there is a wait of twenty minutes or half an hour, when the telephone bell rings again. This time a message comes saying that the doctor has met with an accident and is in need of clothing and naming certain articles of wearing apparel, for which a messenger will call in fifteen or twenty minutes. At the appointed time the messenger appears, and if in the meantime someone in the doctor's household has not been keen witted enough to become suspicious, bears away the articles of clothing that have been asked for.

The National Committee for the Prevention of Blindness held its annual meeting in New York City recently. William Fellowes Morgan presided. It was reported that there are now nearly 4,000 persons aiding the work of the committee in all parts of the country.

Dr. Thomas J. MacFarlane has removed to 1730 72d Street, between 17th and 18th avenues, Brooklyn.

Dr. Julian Bourguet of Paris has arrived in New York to study American methods of plastic surgery.

The Associated Out-Patient Clinics will hold its annual meeting at the New York Academy of Medicine on the evening of Dec. 15. The address of the evening will be delivered by Dr. W. Gilman Thomp-

son, who will speak on the "Present Inadequate Dispensary Service for the Treatment of Industrial Accident Cases."

Obituary Notes.—Dr. CHARLES INFROIT of Paris, a distinguished *x*-ray expert, chief of the Central Radiographic Laboratory of the Saltpétrière, like many of his predecessors in this field, died a martyr to science on Nov. 29. Dr. Infroit was 45 years of age, and for the past twenty-two years has suffered from the results of *x*-ray burns, having undergone during that time twenty-four operations, twenty-two of which were performed during the past ten years. Despite his suffering, he continued to lecture and to attend to his professional duties until very recently.

Dr. FRANCIS A. SCHLITZ, a graduate of New York University Medical School in 1878, died at his home in Brooklyn, N. Y., Nov. 28, at the age of seventy-five. He was for years connected with the old German Hospital and the Deaconesses' Hospital, in Brooklyn.

Dr. NICHOLAS THOMAS BOLEN of Brooklyn, N. Y., a specialist in skin diseases, died of a complication of ailments, on Nov. 28, at the age of fifty-nine. He graduated from the University of Munich in 1891, and came to Brooklyn in 1902.

Dr, JOHN W. COUGHLIN, who served four terms as Mayor of Fall River, Mass., died on Dec. 3, at the age of sixty years. Dr. Coughlin was a graduate of the College of Physicians and Surgeons, Baltimore, in 1885, was a member of the Democratic State Committee from June, 1901, until last June, and was his party's candidate for Lieutenant Governor in 1903.

Correspondence.

POTASSIUM NITRATE IN CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I must again request the privilege of using your columns to answer Dr. Bell's questions propounded to me in his letter of November 13, as published in the MEDICAL RECORD of that date. I wish also to take this opportunity to assure the Doctor of my sincere appreciation of his courteous remarks and well wishes; to thank him for the expression of his amicable views and to further assure him that there is no reason why we may not both express our opinions on the subject of cancer, or any other pathological condition, without raising the ire of either.

Dr. Bell, referring to the chemical reactions between potassium nitrate and sodium chloride, says, "When KNO_3 enters the blood, and when it comes in contact with NaCl, their separate formula becomes altered into $NaNO_3$ and KCl while circulating in the blood. Now these are two basic salts, both having an equal affinity for their acids. How then does the transference take place?"

In 1918 I wrote "A Plea for the Use of Potassium Nitrate in the Treatment of Cancer," which was published in the MEDICAL RERORD for May 4. From it I take the following, and for which most excellent chemical authority can be mentioned; for I might add that before I submitted any problems in chemistry for publication, in relation to a subject as important as cancer, I fortified myself by having such problems verified by chemists whose opinions are considered final. However, the best men may err and the following abstract is submitted for Dr. Bell's consideration.

According to the principle of maximum work in thermo-chemistry, which was demonstrated years ago, whenever several chemical reactions are possible, as the result of the admixture of various chemical reagents, the reaction which takes precedence over all the others is that which leads to the greatest development of heat; or in other words, the particular chemical compound will be formed first whose so-called "heat of chemical formation" is highest; and that compound will also be the most stable, or the most difficult to decompose or displace. When nitrate of potassium composed of potash and nitric acid ions, enters the plasma of the blood, which always contains chloride of sodium, it is possible for a double decomposition to take place, by which potassium chloride and sodium nitrate are formed. Now, it so happens that the heat of formation of potassium chloride is higher than that of sodium chloride, or any other chloride, except that of lithium (which is only about 1 per cent. higher, and is of no special interest in the present connection because it is not a natural constituent of blood or tissue); consequently, according to the established recognized principles of thermochemistry, not only will there be a tendency to the formation of chloride of potassium (by virtue of the principle of the tendency to maximum heat development just mentioned) but this salt will be a more stable constituent of the blood or of any of the fluids or tissues of the body than chloride of sodium.

At the same time that chloride of potassium is formed by the union of the potassium ions with the chlorine ions of the chloride of sodium present in the fluids of the body, the nitric acid ions, let loose or released from the potassium nitrate, will combine with the sodium ions of the chloride of sodium, forming nitrate of sodium. This substance can pass out of the cell tissue into the blood and take part in other chemical reactions in which nitrogen plays an essential role.

An interesting circumstance in connection with the exchange of ions taking place between chloride of sodium and nitrate of potassium, is that the sum of the heats of formation of the two end products remains substantially the same as the sum of the heats of formation of the two initial products. This means that very little energy needs to be supplied from the blood, or from other sources of physical or chemical energies of the body, in order to effect the double reaction just mentioned.

A few abstracts from A. R. Cushny's Monographs on Physiology "The Secretion of Urine" might aid in substantiating the above.

Sollman (1903, page 425) confirms the finding that nitrate injection increases both the percentage and the absolute amount of chloride in the urine previously poor in chloride.

Loewi (1902) observed diuresis from intravenous injection of nitrate, which resembled that from phosphate, except that the chloride excretion in the urine remained high under nitrate.

There seems no question that under nitrate diuresis a larger excretion of chloride in proportion to the other constitutents occurs than under sulphates. Loewi ascribes this to the nitrate dislodging the chloride in the tissues and thus increasing its partial pressure in the

blood; and Langlois and Richet have shown by actual analysis that the chloride of the tissues falls under nitrate treatment. In other words, the nitrate, like the bromide, is not differentiated from the chloride by many tissues, and these exchange part of their chloride for nitrate.

So far I have dealt with the displacement of the chlorides by the nitrates and think I have given good reasons to believe that a transfer between these elements takes place, sufficient to allay any doubt Dr. Bell may feel.

The conclusions arrived at by Bock (1907) after the experiment of injecting "an isotonic solution of potassium salt intravenously in rabbits" is, briefly, "* * * that potassium displaces some of the sodium in the tissues and thus increases its concentration in the plasma and filtrate."

In further substantiation of the displacement of the elements under discussion I would draw attention to the fact that human milk taken from the lactating female, living on a diet containing an excess of salt, is free from potassium. From this fact I am led to surmise that the sodium has displaced the potassium. Might this not be of significance in relation to the fact that sarcoma is found to a greater degree in youth than in middle age, and somewhat strengthen my hypothesis on the physicochemical nature of cancer? For in infancy the nursing child has no access to vegetable matter as food and is deprived therefore of the potassium salts which would, if taken, supply the potassium in sufficient quantity to stabilize the sodium and thus maintain the proper ratio of these two elements. A child reared on a potassium-free diet cannot possess the natural power of resistance to diseases of any nature and would therefore be both deficient and defective.

According to Matthews (Physiological Chemistry, page 310) * * * "all growing organisms need potassium, since potassium in nearly all forms of living matter is present in larger quantities than sodium."

The analysis of human milk by Bunge (Physiological Chemistry, Hammarsten, by Mandel, page 310) shows that the relationship of the two bodies, potassium and sodium, varies considerably (1.3-4.4 equivalents to 1 of soda). "By the addition of salt to the food the quantity of sodium and chlorine in the milk increases, while the quantity of potassium decreases."

In a previous letter Dr. Bell asks, "Does Dr. Robinson believe that the cause of cancer is an excess of salt?" To this I replied that such was my belief; for how can I otherwise believe, when by the displacement of salt with potassium nitrate I see the manifestations of cancer disappear? Dr. Bell in his latest letter says, "My old friend, Dr. Braithwaite of Leeds, advanced the same theory that Dr. Robinson now propounds, over twenty years ago. He believed cancer was due to the ingestion of too much salt, NaCl. But this theory, so far as this country was concerned, fell to the ground as untenable." Unfortunately the Doctor does not give any scientific reasons why Dr. Braithwaite's theory fell to the ground. It therefore gives me great pleasure to defend this theory by offering scientific facts in its support, which I would be glad to have Dr. Bell refute. I am not familiar with Dr. Braithwaite's writings and my premise was not based on his theories. However, history abounds with instances of the revival of old theories once considered untenable, which today are acknowledged facts. Shall we forget that Harvey once said that the blood vessels carried blood and how for one hundred and fifty years physicians insisted that these vessels carried air? Do we not recall that more than twenty-five years elapsed before Lister succeeded in convincing surgeons that pus was produced by germs and that antiseptic treatment was the proper surgical method of treating wounds? Nevertheless, the theory of salt and cancer is tenable and the cure of cancer by the displacement of salt with potassium nitrate is demonstrable and should therefore survive. However, its employment to be effective must be based on known principles and I take the following from my article of May 4, 1918, previously referred to:

There are many important reasons why nitrate of potassium should be administered in minute doses and highly diluted in water. On the one hand, *the introduction of salts of potassium into the blood at too great a rate is objectionable because of the toxic action on the heart;* this action becomes more marked when the quantity of potassium salt contained in the blood exceeds about 1/20th of one per cent. The moment the quantity of potassium salt present in the blood exceeds the proper physiological limit, the excess is worked off through the kidneys by increased secretion of urine containing a higher percentage of potassium than normal. On the other hand, dilution of the solution containing potassium nitrate accomplishes several important objects. First, the process of osmosis by which alone this salt can pass through the walls of the intestine into the blood is greatly facilitated. A strong solution of the salt would indeed pass through only quite slowly, if at all, and the more it is diluted the more readily it will pass. As a matter of fact, the more nearly the solution approaches the specific gravity of pure water the more readily it will pass. What is true of the osmotic action by which passage is effected into the blood from the intestines, is even more true in the case of the osmosis by which substances are transferred from the blood into cell tissues through the walls of the capillaries. It is quite conceivable that although the blood may contain a given salt in considerable amount, very little, if any, of it may pass into the tissues. Indeed, paradoxical as it may seem, in certain circumstances the greater the quantity present in the blood, the slower the rate of its transfer, and therefore the smaller the amount transferred in a given time. This underlying principle of physical chemistry is perfectly well established and should be employed more generally when administering substances whose medicinal effects are dependent upon the property of osmosis.

Second, the chemical reactions on which the therapeutic actions depend are also much facilitated by dilution. The effect of dilution, it is well known, is to produce a state of partial "dissociation" or "ionization" in the elements of a salt held in solution in water, so that some of the atoms are less tightly linked, or less intimately bonded together, in other words, they are partially freed from each other, and exist as "ions," and when in that ionized state they are more susceptible to the action of all reagents and reactions, whether chemical or physiological, which tend to cause chemical changes in them. It is well known that dissociation and ionization render possible many chemical changes and reactions that cannot be produced otherwise.

The foregoing considerations are logical and scientific, applicable not only in this case, but almost in every case where therapeutic agents are to be administered in liquid form. They point to the desirability, in the general case, of not letting the remedial agent cause congestion and crowding, either at the entrance-gate through which they pass into the blood, or at the outlet-gate through which they pass out of the blood into the tissues or into the secretory or excretory organs. A cardinal principle that should be borne in mind is that

it is not the amount administered, but the quantity which can be effectively utilized that counts. Whatever portion has no chance of being effective had better not be administered, for the dual reason that not only is it in the way and prevents the action of the rest, but the task of eliminating the excessive and useless portion may impose more or less serious, and at best always objectionable, work on the heart and the other organs of the body.

Therefore, Dr. Bell will now realize why his prescription of potassium nitrate mixed with molasses and used in the Battersea Hospital in cancer eight years ago was, as he says, "productive of unfortunately only negative results." Applying the adage of Bruce, "Try again," the Doctor might employ potassium nitrate in minute doses.

With the exception of the use of potassium nitrate there seems little difference between Dr. Bell's treatment and that which I employ. The calcium and magnesium are given and I depend on the vegetable substances of the diet to supply iron and other biochemical salts. A very low hypotonic solution of potassium nitrate, whose exact dilution should be determined, (say about 1/120 to 1/60 gr. in 2 to 4 c.c.) is injected intramuscularly not oftener than every other day for a few doses, then every fourth day for a few more doses, and so on increasing the intervals between injections. However, the exact posology is one for the physician to settle. I also give another solution of potassium nitrate orally in doses of one twenty-fifth of a grain in four ounces of water three times daily and this is also gradually reduced. There is no reason to suspect that such doses are toxic, and I have seen no such symptoms. This statement, however, applies solely to the doses and to the solutions I am using. I think it is advisable to mention here that I have seen, on several occasions, considerable swelling at the site of an injection accompanied with tenderness and some heat. A wide hyperemic area with red blotches has been observed in a number of instances. These symptoms I have discovered are due, not to anaphylaxis or to the action of the potassium nitrate, but to the fact that the solution I used was old and improperly made. Accidents of this sort would naturally cause the patient to lose confidence and their frequent recurrence would bring discredit upon an excellent therapeutic agent. Therefore, home-made solutions should not be used unless freshly made and should not contain a preservative agent. The injection of potassium nitrate is free from irritative properties.

It should always be borne in mind however, that, according to Cushney, potassium "is highly poisonous to the heart in anything over 0.05 per cent." He does not state if it is the potassium nitrate salt referred to.

A rest of a week or more and then a renewal of the treatment seems to give the best results. If the injections are too rapidly given some patients may complain of a feeling of lassitude and lose a little weight, while in nearly every instance under this treatment they gain weight. A permanent restriction of salt in the diet is not physiologically wise, for sodium chloride is essential to the economy. An occasional taste of salt, much as animals obtain it, should be allowed. After a restricted salt diet a patient will develop a natural craving for salt which should be satisfied but not to the extent of salting to excess. Ham, bacon, salted fish, and cheeses, and in fact all foods preserved with salt, should be prohibited; otherwise the patient is allowed all other foods, fruit especially.

In my hands this method of treating cancer has shown remarkable results, but I would like Doctor Bell and other physicians to try the treatment so that by the experiences of many we may know whether to accept or discard it.

EDWARD PERCY ROBINSON, M.D.
452 FIFTH AVENUE, NEW YORK.

LONDON LETTER.

(From Our Own Correspondent.)

LONDON, November 12, 1920.

The Annual Report of the Chief Medical Officer of the Ministry of Health.—Sir George Newman, the chief medical adviser to the Ministry of Health, has issued the first annual report of the Ministry. It is a document of the first importance and is besides of considerable literary value. Sir George is the most conspicuous exponent in Great Britain of the principles of the practice of medicine and especially of the principles of preventive medicine. He is, at the same time, eminently sane in his survey of the conditions in this country as regards public and industrial health, and warns his readers not to expect too much from the establishment of a centralized health department. It is impossible to solve at once all the problems of local autonomy and local administration; it is but a step in what he and his colleagues consider the right direction. As he says, "Our business at the Ministry of Health is not to build up for to-day or to-morrow, but for the future; not to attempt to settle forthwith this or that or the other local specific health problem, but to view such problems as parts of a whole, and slowly but surely to lay foundations which will endure. Some of the Ministry's friends and supporters hailed it as an end in itself, as the goal of their desire, as a species of millennium. They expected too much of it, as its enemies expected too little. It represents a reform in central health government, the establishment of a means rather than an end. It cannot provide a remedy for a thousand claims made upon it by well-intentioned persons who have largely misunderstood its purpose. It is a complex piece of machinery which can be judged only in its working, and over a long period of time; to overload and overpress it is to place upon it burdens for which it was not designed. Moreover, it must not be forgotten that the Ministry as such is but a part of an organized scheme for the national health. An organized scheme in any country must include (a) a central supervising department; (b) local authorities or representative bodies for the actual carrying out of the policy of such a ministry in the local divisions or areas; (c) voluntary societies and agencies; (d) an educated people willing and able to practise the way of health. These are four factors, but the foundation of their operations, as well as their direction, must be the advance of our knowledge of the science and art of medicine. Hence there is a fifth factor, the medical practitioner, in some ways the most important and es-

sential factor of all. Upon him, the State has been steadily imposing, for many years, specific duties in regard to the communal health, though it has been slow to associate him closely with its operations. One of the principal objects of a Ministry of Health is to secure his cooperation as an integral and active force in the physical well-being of the nation. The introduction, or part of the introduction, to the report contains the gist of the gospel of preventive medicine and, on the whole, is a good answer to the many criticisms which have been launched against the Ministry and its policy. It is obvious that salvation cannot be found immediately by the establishment of a Ministry of Health, but if wisely directed and not used too much as a political machine, such a department undoubtedly can safeguard the health of a nation to a very considerable extent. Sir George, from a consideration of the available data with regard to British health conditions, draws the conclusion that some gains have been made in the health of the nation, and while the death-rate is declining, there yet remains a serious amount of preventable sickness and disease and avoidable disablement, the tendency of which must inevitably be to have a very deleterious effect upon the physical stamina of the people, reducing their capacity for work and shortening their lives. The broad deductions which may be drawn from the existing state of affairs seem to be as follows: (1) There is a steadily falling birth-rate, which, in 1919, reached the figure of 18.5; (2) there is a death-rate, 13.8, which shows a steady decline at all ages, which raises the expectation of life from birth upwards; (3) the infant mortality rate, 89 per 1,000 births, is one of the lowest recorded, but there is still much unnecessary loss of life both of mother and of child; (4) although the number of cases of epidemic and infectious disease exceeds half a million per annum, the primary burden is relatively light, yet the ultimate results are grave; (5) tuberculosis, measles, acute rheumatism, and influenza are still prevalent, and, with venereal disease, lead to much disablement and mortality; (6) there is also a large mass of disability and incompetency from relatively trivial sickness, much of which is neglected, and thus leads to more serious conditions; (7) the systematic medical inspection of school children has revealed a substantial degree of physical and mental impairment, both the existence and effect of which have been abundantly confirmed by the examination of recruits; (8) the expenditure on sickness and disablement benefit and other similar returns denote that a very serious amount of time is lost from employment, amounting to not less than 260,000 years per annum for the insured population only. It is added that the problem lying immediately before preventive medicine is, first, to rear and maintain a healthy race of people, and, secondly, to continue its attack upon infection and all forms of preventable sickness and invalidity. It is pointed out that the remarkable decline in enteric fever continues to constitute one of the hopeful signs in preventive medicine. In 1869, the year in which typhoid was distinguished from typhus, the former disease had a mortality in England and Wales of 390 per million. In 1918 this figure had fallen to 26 per million. The decline is attributed largely to improved water supply, sanitation, and the protection of food. Water, milk, fish or shell-fish are not inherently concerned with the etiology of typhoid fever. They became concerned as they are polluted, and usually at the source. Gathering grounds of water supplies, dairy farms, shell-fish beds, these are the principal vulnerable points. The writer lays particular emphasis on the need for adequate provision for the care of mothers and infants. Despite the fact that much has been achieved in this direction, the services which have been organized are not complete as yet. The report states, however, that the death-rate of women in childbirth remains approximately what it was twenty-five years ago, and there are lost by death every year upwards of 3,000 women in the fulfilment of one of their principal and most vital duties to the State, a mortality almost entirely preventable. Then, in the next place there is a large volume of abortion, miscarriage, still-birth, and ophthalmia neonatorum, much of it directly avoidable. Again, a substantial number of the 700,000 mothers who gave birth to children in 1919 were so injured or disabled in pregnancy or childbirth as to make them chronic invalids and to bring them in very large numbers to the gynecological clinic or the hospital ward, an excessive burden of preventable invalidity, incapacitating in its immediate and deterrent in its remote effects. It would be difficult, according to the report, to overestimate the vast mass of suffering, disability and incapacity which is thus caused and which ought not to be caused. Lastly, there is still lost by death not less than 60,000 infants in the year, excluding 19,000 still-births. In order to successfully cope with these conditions it is urged that the efforts put forth persistently and consistently in every district throughout the land must be concerned with the efficiency and adequacy: (1) Of methods for the supervision of pregnancy; (2) of midwifery; (3) of maternity homes and hospitals; (4) of home nursing and health visitors; (5) of infant welfare centers and institutions, and (6) of the sound administration and wise use of maternity benefit. Stress is laid on the point that no panacea will meet the situation which can be met only by a comprehensive movement, universally accepted and steadily pursued. Sir George further holds that the final issue can never be in doubt. The State cannot afford to be careless or negligent of motherhood, it cannot afford to leave its infant life to chance or the misfortune of circumstances. There must come a time when civilization means that no child-bearing woman is without adequate and skilled assistance, and no infant without a birth-right of health. That time should come in England first among all nations.

I shall refer to this report again because, while it concerns Great Britain most intimately, it really is of the first interest to every civilized nation.

Scarcity of Nurses.—A report of quite exceptional interest with regard to the shortage of applicants for training as nurses was presented recently by the matron of the London Hospital to its House Committee. It was pointed out that

nursing to-day is not merely a matter of making beds and smoothing pillows. For years past doctors and nurses have worked together for the benefit of their patients, and never more so than at the present time. Whatever new schemes of reorganization may change the systems of the hospitals, it is manifest that they cannot exist without their efficient staffs of nurses, while in national health and the fight against preventable disease they will also be essential. But what, perhaps, neither the head mistresses of girls' schools nor the girls themselves are quite realizing as yet, is that if the nurse is to take her right place among the professions she must be placed on a higher level than the cook and the scullery maid as regards pay. She must see more good appointments ahead of her. Some real inducement is needed to encourage people to enter the nursing profession and to remain in it, something to work up to and worth striving for. The nursing profession cannot be ignored in this fight to improve the health of the nation, and it is imperative that it be given its right status with other professions. It was with this end in view that the Weekly Committee of the London Hospital agreed to a reorganization of their entire system of nursing, with increased salaries extending to the whole staff, from the highest ranks down to the last joined probationer. The matron is, in future, to be relieved of much detail and routine work by the appointment of two assistant matrons at adequate salaries. The scale of pay, which is generous, places nursing on a more satisfactory basis than ever known before. The nurse has now her own private bedroom, comfortably furnished, and has the use of spacious living rooms. Board and washing are provided, as well as medical treatment if necessary. And last but not least, there is a pension assured after twenty years' service, a pension adequate to provide ease and comfort for declining years. Under this scheme of reorganization, nursing offers favorable possibilities and may be compared with advantage with such work was teaching, for example, on the business office or private secretarial work—no longer will nursing be regarded as of yore as a vocation of self-sacrificing devotion, in which money rewards played no part. Nursing is now looked upon as a profession working in alliance with medicine and surgery and paid accordingly.

5. The Early Orthopedic Treatment of Infantile Paralysis.—Arthur T. Legg describes the methods of treatment which have been found successful in caring for the victims of the 1916 epidemic, and emphasizes the principles brought out by a careful study of the progress of more than one thousand cases. The summary drawn from this experience follows: During the sensitive stage the patient should be at perfect rest. No active treatment should be started until tenderness has entirely disappeared. All beginning deformities should be corrected as soon as they appear. An accurate muscle examination of the entire body should be made before starting any treatment. Sitting and walking should be prohibited for two or three months at least, and then allowed only when the patient can be kept in a normal position. Braces should be applied, (1) to prevent deformity; (2) to allow locomotion. Fatigue must be constantly guarded against. Massage and muscle training is the best method for re-establishing power.

2. Standardized Röntgen Ray in the Treatment of Skin Diseases.—Howard Fox considers the standardization of the roentgen ray one of the greatest advances in dermatological therapeutics. His conclusions from a review of its uses are as follows: (1) The roentgen ray is probably the most useful therapeutic agent for the treatment of skin diseases. (2) Its versatility is shown by the great variety of conditions in which it can be used, including inflammatory diseases, those depending on epilation, pruritus and hyperidrosis, lymphatic disease and cancer. (3) It is only by means of accurate standardization that its full value can be realized and its dangers eliminated. (4) Standardized treatment requires the use of a Coolidge tube and interrupterless transformer. The quantity of ray can then be measured by pastilles or by arithmetical computation. (5) The routine use of pastilles is unsatisfactory, as considerable experience is required and as they introduce the element of personal equation. (6) by means of the simple method of computation devised by Mackee and Remer, the treatment of skin diseases by the roentgen ray has been revolutionized and a great contribution made to dermatological therapeutics. (7) The most brilliant results in the writer's experience have been attained in eczema and in ringworm of the scalp, where the roentgen ray is certainly the method of choice. (8) It has also been of great value in acne, psoriasis, seborrhoic eczema, lichen planus and epithelioma. (9) In chronic sycosis, localized hyperidrosis and some cases of localized pruritus it is the only remedy (except radium) that can effect a permanent cure. (10) Leucemic conditions and mycosis fungoides cannot be even temporarily improved by anything except the roentgen ray (or radium).

2. Actinomycosis Treated with Methylene Blue and Roentgen Ray.—Jensen and Schery, believing that methylene blue might prove to be a specific for *Actinomyces* in the human being as well as in the test tube, used this agent in a case, report of which is given. They found that the combined treatment, consisting of methylene blue and the roentgen ray, which is new in the literature, clears up the condition. Either roentgen ray or radium is probably sufficient as a curative agent.

5. Gonorrhea of the Lower Genito-Urinary Tract in Women.—Stevens and Heppner have made to date 3439 examinations and found chronic gonorrheal infection in 1496, or approximately 43.5 per cent. In the first 2375 cases the diagnosis of gonorrhea was based on the detection of the organism in the smears or the presence of a ++ or +++ positive complement fixation test, together with characteristic clinical findings. Many cases were doubtlessly overlooked even in those subjected to repeated examinations; for the difficulty of detection of gonococci in women, especially in chronic infections, is universally recognized, and the fallibility of the complement fixation test in its present form is likewise understood. In the last 1064 examinations positive clinical findings were usually considered sufficient evidence of gonorrhea in these patients. The correctness of this assumption was justified by the discovery of the gram-negative organisms in approximately 95 per cent. of these patients at some time during their stay in the hospital. The infection was located in the cervix in approximately 47 per cent., in the urethra in 32 per cent., and in one or both Bartholin glands in 23 per cent. of these cases. Smears from the vagina were never positive in the absence of infection of the cervix. In the presence of cervical infection the complement fixation test for gonorrhea was positive in approximately 59 per cent., in urethral infection in 23 per cent., in bartholinitis in 19 per cent. of these patients. In the last fifty patients examined, however, the complement fixation test was positive in every case regardless of the location of the infection. The same antigen was used in all. Because of the fact that, unlike acute gonorrhea, chronic infection of the genito-urinary tract in women is seldom productive of subjective symptoms, reliance must be placed entirely on objective symptoms for a diagnosis. Very few cases of acute gonorrhea were found in this series of examinations. From this study the writers draw the following conclusions: Gonorrhea in women occurs more frequently than is generally appreciated, and should be accorded more attention than it has heretofore received. The persistence of gonorrheal urethritis is usually due to glandular involvement or stricture at the meatus or within the canal. Strictures of the urethra, usually at the meatus, are common and should receive appropriate treatment. The ducts and glands of Bartholin are frequently infected by the gonococcus. Injections are of little value in the treatment of infected glands. Urethral glands must be destroyed and Bartholin glands excised. The entire Bartholin gland must be removed; otherwise, subsequent abscess formation is liable to occur. Neither absence of demonstrable gonococci nor occlusions or strictures of the ducts are contraindications to the removal of the glands of Bartholin.

11. Indol Test on the Spinal Fluid for Rapid Diagnosis of Influenzal Meningitis.—T. M. Rivers reports that eleven of twelve meningitic strains of *B. influenzae* studied were indol formers. An indol test on spinal fluids is a valuable aid in the rapid diagnosis of influenzal meningitis.

2. An Address on the Unity of Medicine.—C. O. Hawthorne, in this introductory to the post-graduate session of the Central London Hospital for Diseases of the Throat, Nose and Ear, says, with regard to "teamwork" in medicine—a phrase that he calls one of the idols of the hour—that it is true in so far as it implies that no one man can pretend to compass fullness of knowledge or of skill in all departments of medical work. Hence, for scientific investigation and research, the division of labor is advisable and even necessary. It is to be remembered, however, that the immediate business of practical medicine is neither the demonstration nor the verification of scientific truths, but the care and protection of the individual patient. For his part, he would cultivate a sense of acute sympathy for any sick man who was placed under the care of a "team" of experts. In the charge of a patient, whatever contributions may be obtained from other sources, there is required for purposes of safety one supreme command by which the final and governing word may be spoken and one individual judgment carrying full responsibility and demanding the natural corollary of full responsibility—unchallenged and unquestioned authority. In medical practice the study and treatment of local disturbances cannot, either on prudential or on scientific grounds, be justifiably divorced from the cultivation of a full diagnostic ambition. Making the application of his views on the subject to otolaryngology, Hawthorne says suppurative disease of the middle ear carries, as is admitted, the risk of intracranial complications which may in individual cases demand prompt and serious operative procedures. In some instances the evidence is plain beyond challenge; in others the evidence is so slight or doubtful that even an experienced judgment is compelled to hesitate. Suppose, in such a position, the ophthalmoscope is used for the first time and double optic neuritis is discovered. The fact surely has an alarming quality in reference to the issues which are at stake. But it is not conclusive if double optic neuritis is found in a certain proportion of cases of middle ear disease without other evidence of intracranial development, and if the neuritis in some such cases disappears apart from intracranial operation. Considering the bearing of such a conclusion in the case of middle-ear disease with balanced evidence of some intracranial extension and with the discovery of the existence of double optic neuritis, is it not evident, he asks, that in such circumstances it is an almost vital point to be able to say whether the optic neuritis is or is not a new fact? But no one can make this statement unless he has examined the fundus oculi at a date anterior to that on which any question of intracranial complication arose. Hence, though it may seem a hard doctrine, there is no escape from the conclusion that every patient who is under treatment for disease of the middle ear ought to be made the subject of ophthalmoscopic examination, just as the same practice applies to sufferers from anemia or chlorosis. And both these lesser exhortations, it is concluded, come under the sway of the general and commanding truth that completeness of examination is to be encouraged not only for the protection of the patient, but also for the entertainment, the education, and the mental comfort of the physician.

3. A Note on Our Present Conception of Psychological Repression.—Henry Yellowlees takes a "fling" at uninformed critics of psychoanalysis, disposes of the fancied parallel between the psychoanalytical consulting room and the confessional, considers the difficulties of psychoanalysis, gives an instance of repression, discusses repression and forgetfulness, primary and secondary mental systems, and intra-psychic conflict, then concludes, in part, as follows: Repression, as here discussed, is not to be regarded as in any way a pathological or abnormal process, but as one which is natural, universal, and, indeed, essential in training and education. The limits of the normal are only passed by the natural process going to abnormal lengths, or, more frequently and importantly, by the devices adopted by

repressed material to overcome or evade the repressing force. Such events occur in neurotic persons, and are the stuff of which their symptoms are made. The writer holds no brief for psychoanalysis, but he believes the critic should at least have read up, if not practised, the subject he is criticising. He also offers the suggestion that if the authorities on psychoanalysis could see their way to expounding the essentials of their subject with a little more simplicity and patience, much good would result and much criticism would be disarmed.

2. Notes on Blackwater Fever.—Alexander Goodall tabulates fourteen cases, in twelve of which malarial parasites were found. All the cases were treated with large doses of quinine and twelve recovered. It is contended that malaria is the essential cause of blackwater fever, and that exposure to cold may be an important factor in determining its onset.

3. Resuscitation in Death Under Anesthesia.—Welby Earle Fisher advocates resuscitation by means of cardiac massage, reminding the reader that beyond the period of half an hour no measure whatsoever will avail. He describes the methods of performing cardiac massage as follows:

Subdiaphragmatic Massage.—In this method an opening is made in the epigastrium to the left of the middle line, and large enough to admit a hand, which is passed, palm upwards, between the left lobe of the liver and the diaphragm. The fingers are pushed well backwards and upwards against the left cupola of the diaphragm, and a forced jabbing movement is made behind the ventricular region of the heart, so as to squeeze it effectively against counterpressure made by the other hand on the precordial region of the chest wall. The compressions are repeated at a rate of about forty a minute (a more rapid rate is not practicable), and are carried on until the heart-beat is re-established with regular rhythm and maximal power as reflected in the pulse. The abdominal wound is then sutured.

Transdiaphragmatic Massage.—This is a technique devised by Captain T. C. Bost. The abdomen is opened as before, and the further steps are only proceeded with if subdiaphragmatic massage fails. The costal attachment of the diaphragm is divided sufficiently to force an opening into the left pleural cavity, through which the right hand is insinuated, and the heart grasped and squeezed as it lies in its pericardial sac. Artificial respiration must be carried on throughout the operation.

Transpericardial Massage.—This very difficult method has not in practice met with gratifying results. A flap of precordial thoracic wall is raised, the pericardium opened, and the heart directly squeezed.

Supradiaphragmatic Massage.—This method affords ready access. A lower intercostal space on the left side is quickly opened by a lengthy incision, well retracted, and a hand is introduced into the left pleural cavity. The heart, enclosed in its pericardial sac, is grasped and squeezed. The writer has seen no mention of such an operation being designed to meet the occasion. With failure by subdiaphragmatic massage it arises as an alternative to the method designed by Captain Bost, who claims as an advantage of his plan that occurrence of pneumothorax is practically precluded by the close fit of the diaphragmatic opening to the wrist, and that artificial respiration can be efficiently carried on. The writer records the histories of six cases.

2. Therapy of Certain Gastric Conditions. Frank W. Foxworthy.
3. Formulae and Things Therapeutic. Leo A. Dorn.
4. Anesthetic Notes. Arthur E. Guedel.

1. The Diagnosis and Treatment of Ectopic Pregnancy.—E. E. Padgett summarizes his views on this subject as follows: 1. Ectopic gestation is more commonly present that diagnosed. 2. The condition is always caused by some pathology in the generative system, which should be made out by examination and the condition corrected before the abdominal pregnancy occurs. 3. Many cases never come to operation because they never cause severe hemorrhage, terminating as a uterine abortion, a tubal abortion without serious hemorrhage, death of the fetus before rupture, or a rupture without serious hemorrhage unto the broad ligament. 4. The diagnosis is most often confused with an early uterine pregnancy and depends upon a careful study of history and early symptoms for its differentiation. 5. A woman in the child-bearing period who has always been regular, having failed to menstruate for one or more months, is probably pregnant, and a return of the menstruation usually means that she is going to rid herself of an abdominal pregnancy, regardless of where it is located. 6. These cases are all surgical. 7. The time to operate is before rupture has taken place. 8. Rupture into the free peritoneal cavity is the condition to be most feared, as it is always sooner or later followed by extreme bleeding and calls for early and rapid operation. 9. After such a rupture cases which show improvement in the pulse need not be termed emergency operations, but should be operated upon as soon as the general condition improves. 10. Intravenous salt solution or blood transfusion is good practice after the bleeding has stopped, and there is no objection to the use of medication which will help control the bleeding. 11. Very few women actually die from this condition.

Wiener klinische Wochenschrift.

October 7, 1920, xxxiii, 41.

Histology of the Gonads in Homosexual Men.—Steinach's article appeared originally in the *Archiv fuer Entwickelungsmechanik der Organismen.* Bd. 46, Heft 1, and is reviewed in the above journal by Kyrie. Steinach's name is much before the public in these days in connection with youthful regeneration by implantation of the gonads and commercial companies are said to have been organized to exploit this idea. This scientist, however, is primarily an embryologist who has produced hermaphrodites experimentally and who was the first to inspire the idea of testicular grafting as a cure for homosexuality. The original idea of the latter was that of a purely psychic alteration but Steinach has shown that the gonads of these men, although in most cases apparently fully developed, are histologically abnormal: certainly in all congenital cases, or in other words in true inversion. The field opened up is considerable, for homosexuality masked during life may be revealed at autopsy and after castration. It has always seemed singular that inverts even when they copulate with women are almost always sterile. A few supposed homosexuals like Wilde have begotten children and from this viewpoint Wilde was not a true invert but a pervert. The histological alterations found by Steinach are naturally those of degenerative or atrophic character as far as the seminiferous structures are concerned, while in the interstitial portion large cells resembling the lutein cells of the ovary may be seen. The earliest experiments in grafting normal testicular tissue into homosexual men, presumably after castration, inspired by Steinach, are said to have been completely successful in transforming inverts into sexually normal men, but in the present review there is no mention of these results.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Forty-Fifth Annual Meeting, Held at Chicago, Illinois, October 26, 27, and 28, 1920.

THE PRESIDENT, DR. FRANK B. WYNN OF INDIANAPOLIS, IN THE CHAIR.

President's Address; Present Trends in Medical Practice.—Dr. FRANK B. WYNN of Indianapolis stated that specialism had led the way in modern progress; no less in commerce and manufacture than in science and art. Medical specialism had grown with phenomenal rapidity and the question was where would it end? Medical schools had been a potent factor in the spread of its teachings. Unfortunately medical students had come to look upon specialists as a group of the elect in medicine, whilst general medicine was viewed as the recourse of the mediocre and unambitious. Even the general practitioner had become obsessed with the feeling that he had lost the prestige and esteem of former days. Dwelling in the slough of despondency he was prone to yield to the temptation of rebating and fee-splitting—practices repulsive to the medical conscience. Disparity in the net incomes of specialists and general practitioners was more apparent than real. Specialists had a shorter earning period, spent extravagantly in keeping up appearances and gaining a reputation, and seldom ended their careers full-handed. General practitioners had a longer earning fastigium, more stable income, learned habits of frugality and lay by a comfortable sum for declining years. More serious than the economic phases of specialism in its trend toward materialism was the tendency to forget the body as a whole. Just as the piece-worker in a factory lost interest in the machine of which his part was a unit, so the medical specialist in his hot pursuit of cold facts in a limited field, lost ardor for the sentimental, moral and spiritual elements of man as a whole. He was prone to atrophy of the moral and spiritual sense of reverence for the human body and human life. From time immemorial the idealistic conception of medicine was that human life was a sacred thing—whether *in utero*, in the matured individual of amazing complexity and power, or the aged seer rich in achievement. With such a conception one should view wanton mutilation of the body in the name of surgery, as criminal. To those of thoughtful mind, it was disheartening to observe the insidious hardening of the medical conscience; to note the haste and lightness of thought with which major surgical attack was advised and undertaken. Very often short-cut methods were pursued. "We will open the abdomen and see" expressed the unscientific procedure followed. Turning from this critique of specialism it might be asked what was to be done to rescue the general practitioner from despondency, self-depreciation and inertia? How should he adapt himself to the changing conditions of the time and keep progress with specialism? First, he must be brought to realize that his job, rightly performed, was bigger than any specialty. Let medical colleges exalt the dignity of general practice, teaching the fundamentals and methods of general diagnosis to the degree of a fine art, leaving the specialties essentially for post-graduate work. The chief business of the medical college was to produce general practitioners—not specialists. There must come a more intimate mingling of those engaged in general practice which would beget enthusiasm, clinical alertness and scientific morale. General and special practitioners should cooperate to a larger degree—in the medical society; through cooperative medical libraries and medical review clubs. Thus would the scientific leaven mingling with that of good fellowship finally leaven the whole professional lump—promoting the traditional ideals of medicine and bringing us a little nearer the brotherhood of man.

Surgical Treatment of Peptic Ulcer.—Dr. CHARLES H, MAYO of Rochester, Minn., said that ulcer in both the stomach and duodenum was an accident which occurred but rarely, but in the aggregate affected thousands of persons. Many of those affected experienced but little trouble and in some the condition was not diagnosed. As a rule, the symptoms were definite and easily recognizable. An *x*-ray diagnosis might be made in 95 per cent. of the cases. Peptic ulcer was three times as common in males as in females and duodenal ulcer four times as common as gastric ulcer. From January 1, 1906, to January 1, 1920, 1,191 patients were operated on in the Clinic for gastric ulcer and 4,532 were operated on for duodenal ulcer, and in 203 instances ulcers were found in both regions. The condition might result from bacterial embolic infarction interfering with circulation or from chemical action causing local vessel spasm. The influence of changes in crystaloids, colloids, or through cell electrons might be an important factor. The chronicity was undoubtedly maintained by the chemistry of bacterial products. The ulcers were not traumatic; they commonly occurred in the circulatory areas nourished by terminal arterioles. Gastroenterostomy gave a high percentage of cure, but it should not be made without positive evidence of ulcer. Ulcer of the stomach might become malignant; ulcer of the duodenum did not. The operation preferred in the Clinic was excision or cautery destruction of ulcer of the stomach and destruction of all duodenal ulcers that caused hemorrhage. Gastrojejunal ulcers, while rare, might be avoided largely by the use of absorbable suture material. The operative mortality in the 4,532 cases of duodenal ulcer was 1.76 per cent. Sleeve resection was recommended in hour-glass contractions of the stomach from ulcer, with excision of the lower portion in the rare cases of recurrence, and in extensive ulceration and thickening of the pyloric region resection of the involved lower one-third of the stomach with anterior gastrojejunostomy, and end-to-side attachment was recommended.

Pernicious Anemia with Especial Reference to Treatment.—Dr. WILLARD C. STONER of Cleveland, Ohio, said that it was difficult to rationally treat disease, the cause of which was unknown. In the treatment of pernicious anemia his therapy was determined by symptoms present and not etiological indications. The cause of pernicious anemia was as much a mystery as it was in the days of Biermer or Addison. It was difficult to determine the value of treatment for the reason that the disease tended to remissions without treatment. An early diagnosis was not always easy to make and a final diagnosis could only be made after a period of observation. Early gastrointestinal and neuro-involvement had suggested an infective condition and foci of infection had been emphasized. There was no specific therapy. Accepted treatment consisted of (1) a rest cure with dietetic régime of high caloric feeding; (2) The use of arsenic in some form; (3) The eradication of foci of infection; (4) Transfusion; (5) Splenectomy. Rest and forced feeding were extremely valuable. Arsenic and dilute hydrochloric acid were good adjuncts. Intravenous arsenical therapy was preferable. Blood transfusion in the way of small repeated transfusions was important, but forced feeding and rest would often do better. Splenectomy as a therapeutic measure had been disappointing. Sooner or later all methods of treatment would fail. Nature was a good doctor and we were unable to absolutely measure the value of any particular management but experience taught us that rest and forced feeding had first consideration.

Tumors of the Bladder (Pathology).—Dr. A. S. WARTHIN of Ann Arbor, Mich., presented the pathological findings in a series of cases of tumors of the bladder representing the most common types of bladder neoplasms as found in the service of the University Hospital, Ann Arbor, Mich. These cases included papillary epitheliomas, malignant transformation of the malignant papillary epithelioma, primary medullary squamous cell carcinoma, secondary scirrhous carcinoma from primary of the prostate and a series of cases of congenital myxosarcomas of the bladder and prostate. From the bladder tumors examined in the Pathological Laboratory of the University of Michigan, he concluded that his experience was different from that given in the usual textbook article on bladder tumors. As regards the occurrence of the papillary epithelioma and the primary carcinoma of the bladder with reference to sex, the majority of these tumors had been found in the female, whereas the textbook articles stated that they occurred much more frequently in the

male. This type of neoplasm was the most frequent one found in the bladder. It was of slow growth but eventually tended to become malignant and to infiltrate the bladder wall. Only extremely rarely did it set up metastases and these were found in the pelvic lymph nodes. Every stage of transition was shown between the simple papillary fibro-epithelioma and papillary medullary squamous cell carcinoma. From the pathological standpoint, the prognosis in the cases of these neoplasms was good, and if they could be removed earlier and without too much injury to the bladder or ureters, the prognosis should be considered as very good. Next to the papillary epitheliomas and carcinomas developing from them were the primary myxofibromas and myxosarcomas, which in all cases had been found in young boys. These were extremely malignant and recurred very rapidly after operation and tended to produce generalized metastases. The prognosis was extremely grave. These cases increased in malignancy on repeated operation and he had seen a tumor originally showing the histological structure of a myxofibroma take on the structure of a myxosarcoma and finally that of a spindle cell sarcoma, which grew out of a laparotomy wound and infiltrated the bladder wall. Metastases in the blood spaces of the penis were extremely common with these, and priapism had been observed in a number of cases. The origin of these neoplasms was always from the trigonum. They sometimes contained striped muscle cells and occasionally cartilage. They were undoubtedly congenital teratoid growths and their origin to be referred to remains of the Wolffian body. He was also inclined to ascribe a congenital origin to the papillary epitheliomas. After these two varieties of neoplasm which the writer found most frequent in his experience were the secondary carcinomas invading the bladder from either the prostate or uterus. In several cases of the so-called Krukenburg tumor, metastases of the stomach cancer were found also throughout the bladder wall as in the ovaries.

Birth Rates and World Wars.—Dr. C. A. L. REED of Cincinnati stated that the underlying cause of the World War was the necessity for land and food by overpopulated countries. In certain features, and contrary to its declared purpose, the treaty of Versailles was a fatuous attempt to repeal the law of nature underlying racial existence. If, instead of stimulating reproduction in violation of the fundamental laws of morality, the afflicted nations of Europe had formulated instructions to their peoples how voluntarily and safely to regulate their birth rates and thus reduce their populations to a self-supporting basis and keep them there; if the Versailles plenipotentiaries had done this they would have given the world the only possible guarantee against war and would have immortalized themselves by an act of transcendant statesmanship. The influences left uncorrected at Versailles made another world war inevitable, league or no league. It would be as much larger and more murderous than the last one, as the populations fighting for "a place in the sun" would be larger than those engaged in the last conflict. It would come with a rapidity precisely relative to the excess of birth rates over death rates. The birth rate in the United States had been practically uninfluenced by the war. It was 22.3 per thousand of population. These figures were based upon official returns, personally secured, from the registrars of vital statistics in thirty States. These States embraced all of those contained in the vital statistics registration area of the United States for 1918, and, in addition, the States of Alabama, California, Colorado, Delaware, Louisiana, Mississippi, Missouri, New Jersey, South Carolina, and Wyoming. This large area, embracing the majority of the States, and the vast majority of the population, might be taken as an average for the whole country. This decline of less than one-third of one point showed the aggregate influence of the World War on reproduction in this country. Even this small decline was largely accounted for by the returns from the State of New York, in which alone there was a sharp fall from 24.2 in 1914 to 20.8 in 1919. This decline in New York was accounted for by the suspension of immigration, war service, and influenza, all of which conditions were especially acute in that State. If one discounted the statistical aggregate for the whole country by these facts from New York, he would discover that our national birth rate was rather higher since than before the war. The following were Dr. Reed's conclusions: "1. The rapid growth of population, everywhere more rapid than is conducive to world welfare, justifies the teaching of safe contraceptive methods, and this teaching is a natural function as it is a moral obligation of the medical profession. (2) Contraceptive methods that are not hazardous to either the individual or to society are not only justifiable but are demanded as safeguards against abortion and feticide, both of which ought to be punished by extreme penalty of the law. (3) Any statute that may interfere with the medical profession in the discharge of its duty in this or any other regard ought to be observed while it is on the statute books, but every possible effort should be made, not by the medical profession alone, but by society at large, to secure either the necessary amendment or enlightened judicial interpretation, or, in the absence of these, the repeal of such statute. (4) In the instance of persons applying for relief from infertility it is our professional duty, first, to disregard any sociologic views that we may entertain as applicable to the individual case; second, carefully to examine the case with reference to the active present cause; third, explain the situation frankly to the parties concerned; and, fourth, bring all the resources of the medical and surgical art to bear upon a restoration of the function."

Cooperation Among Physicians.—Dr. HENRY A. CHRISTIAN of Boston, Mass., said that one of the very fine things of the American Medical Association had been the work of the Council on Medical Education. It had been a constructive force in the improvement of medical schools, and by continuously bringing its work before the medical profession through the *Journal*, it had aroused a widespread interest which had been extremely helpful in bringing about improved conditions. Furthermore, it had coordinated a number of agencies working in this field. The work had been fine, and if there had been any mistakes, as seen from an individual viewpoint, they had been of minor import, and only such as would have been made by any group undertaking such a large work and, after all, they had been but few. Now their work was being extended to a collective study, constructive criticism, and standardizing improvement of hospitals, a work in which the American College of Surgeons was taking an active part. This study came nearer home to a large group of the profession than their investigation of medical schools, because a large proportion of the medical profession served on hospital staffs. If these two efforts succeeded in their aim, they would need the active support of the general medical profession and the value of these moves was deserving of our every cooperative effort to make them succeed. The members of the medical profession should keep in touch with what was being done and should willingly cooperate. The only danger from these efforts to standardize medical education and hospital practice lay in stereotyping methods with a resultant feeling that only along certain lines could progress be made. It was necessary to recognize that every opportunity must be afforded for a free initiative in the trying new methods. Rural practice was in a serious condition. In much of the country rural populations had inadequate medical service. Country practice of the present type failed any longer to attract recent graduates in medicine. Statistics showed not that there were too few physicians; but that they were too unevenly distributed; too few in the country, too many in the cities. Rural practice must be made more attractive. Local cooperation and the establishment of community medical centers would seem likely to improve these conditions. The rural community high school suggested the possibility of something similar for medicine; a well equipped community hospital, visiting nurses, visiting physicians, proper transportation from home to community hospital, community health work, herein lay a possibility of medical practice that would attract and hold the well-trained physicians by affording them excellent facilities to do their work in rural communities.

The Present Status of Preclinical Branches.—Dr. LOUIS B. WILSON of Rochester, Minn., stated that the

present status of laboratory branches constituted a serious menace to medicine. Without proper training in the fundamental branches, the medical graduate was permanently handicapped. There was scarcely a medical school in the United States which had a fully manned department in any of the fundamental branches. The principal causes of depletion of personnel of preclinical branches were as follows: (1) The head of a fundamental department in a medical school nearly always was and perhaps always ought to be a medical graduate. Thus, his preliminary scholastic training had required of him at least two years more than that required of the man with the degree of doctor of philosophy who was teaching in academic departments of the university. He was usually several years senior to the head of the academic department before he obtained his full professorship. Yet in those medical schools connected with universities there was a growing tendency to hold the head of the medical department on the same pay basis as that of the head of the academic department. (2) The present movement to pay full-time clinicians larger salaries than the men in the preclinical branches was a serious source of discontent. The remuneration of men in preclinical branches must be raised to that of men doing full-time work in clinical subjects. (3) The laboratory man on a whole-time basis had rapidly become a no-time clinical man. Whether this was in the best interests of medical teaching was a debatable question. Whatever one might think of the general proposition, certain it was that the laboratory men who had been cut off entirely from the clinical side of medicine had come to be regarded as financially unproductive, and had even been referred to as "parasites" on the clinical departments. Such an attitude was keenly resented by and red-blooded laboratory man and constituted a substantial reason in some instances to deter high grade men from going into laboratory branches for a life work. (4) During the war many laboratory men were placed in work quite different from that of their classrooms, and almost to a man they made good. Thus they came to realize that they could readily change from laboratory work into some work with less drudgery and more kudos. (5) Graduate students in fundamental branches had been getting fewer and fewer. At the same time there had been a tremendous increase in the number of undergraduate medical students. Many men who formerly were willing to stay in fundamental laboratory work because of the opportunities for research and for stimulating it in others were now leaving the laboratories because no time was left for their own research and because there were few high grade graduate students for them to direct in investigative work. The combined result of all these factors was already showing in the defective preparation of many medical graduates. Chemistry, anatomy, physiology, pathology, and bacteriology were probably not so well taught in most of the medical schools of the United States to-day as they were five years ago. The effect of this on the entire field of medicine was serious and must become more so. The following suggestions were offered: (1) Perhaps, at present, budgets sufficient to pay the head of each fundamental department a salary of $10,000, the associate professor $7,500, assistant professors $5,000, enough instructors $3,000 or $4,000, and teaching fellows $1,000 to $2,000 would meet the financial necessities. In most institutions this would mean an annual salary budget of $40,000 to $50,000 for each of the five fundamental branches. The Regents of the University of Minnesota had recently increased the stipends of Fellows (medical graduate students), majoring in fundamental branches to $900, $1,200 and $1,500 for the first, second, and third years respectively, while Fellows in clinical branches received only $600, $750, and $1,000 each year respectively. This, at least, was a start in the right direction. (2) The university hospital must provide increased opportunities for the laboratory men to come in contact with patients either for investigative or consultation work. The members of the association were urged to do four things: (1) Read the full report of the Committee of the Division of Medical Sciences of the National Research Council in the *Journal of the American Medical Association* for April 17, 1920. (2) Lend their active personal influence to secure the diversion of as large a proportion as possible of the funds of medical schools with which they might be connected to the support of the preclinical departments therein. (3) Make every effort possible to secure increased appropriations and private bequests for adequately financing preclinical departments. (4) Provide means even at personal sacrifices whereby their medical associates working in preclinical fields might be given a direct interest in the fields of clinical medicine.

Diagnosis and Treatment of Iritis.—Dr. ALBERT E. BULSON, Jr., of Fort Wayne, Ind., said that errors in the diagnosis and management of cases or iritis were quite common and due in a large measure to the superficial ophthalmological training which the average doctor and even some so-called specialists received. Attention was called to such cardinal symptoms as circumcorneal injection, pain, disturbance of vision, alteration in the color and appearance of the iris, contraction of the pupil, and adhesions, and the methods of differentiating this disease from uncomplicated conjunctivitis and acute congestive glaucoma. Hyperemia of the iris was one of the mildest disturbances, and was considered merely a symptom and not a disease, but should be recognized early and given attention by local applications of atropin which acted as a sedative and had a tendency to prevent actual inflammation of the iris. The essayist stated that he did not believe there was any such a thing as primary or idiopathic iritis, but that the disease was always secondary in that it was one of the manifestations of the action of a toxemia or an infection. He, therefore, urged that more attention be given to thorough general examination to determine the cause of the disease in order to intelligently prescribe treatment. Syphilis, which caused from 40 to 60 per cent. of the cases of iritis, should be diagnosed definitely by the Wassermann reaction, and corroborated by the clinical manifestations. Emphasis was placed upon the fact that gonorrhea accompanied syphilis so frequently that sometimes the iritis was due to a combination of the two types of toxemia, and treatment must be applied accordingly. For the purely syphilitic cases neosalvarsan intravenously and mercury by inunctions to the point of tolerance was urged. Locally, atropine solutions to the point of tolerance were advocated, providing the mild solutions did not dilate the pupil. Pure powdered atropine oftentimes could be used, and was indicated in some cases after determining the susceptibility of the patient. If gonorrhea was a complication, as determined by the complement fixation test, vaccine should prove beneficial. Most of the other types of iritis were considered as a manifestation of a general toxemia due to infection by streptococci and similar organisms located in the joints, about tooth sockets, in the tonsils, in the accessory nasal sinuses, in the genitourinary tract, or even in the gastrointestinal tract. The complement fixation test was of great value in showing the presence of the *Streptococcus viridans* which so often was a causative factor, but was of questionable value in determining the nature of other microorganisms. Many of the cases of recurrent iritis were due to a toxemia arising from infected processes in other portions of the body which must be removed before the eye trouble was controlled. Emphasizing the necessity for a painstaking and thorough general examination in order to prove up the etiologic factor, meant a process of elimination through the results secured from blood examinations, urinalyses, and complement fixation tests, any or all as might seem required, coupled with the deductions drawn from the clinical findings. The physician who confined himself too closely to the local treatment and neglected to take into consideration the systemic disturbances, was bound to fail in obtaining the best results. The laboratory technician was a necessary aid in determining the etiology.

Unusual Vasomotor Disorders.—Dr. WALTER L. BIERRING of Des Moines, Iowa, said that vasomotor phenomena observed in disease conditions continued to have an obscure pathological basis and were equally difficult to explain etiologically. Physiologists distinguished two varieties of vasomotor nerves; vasoconstrictors, and vasodilators, the latter having as yet acquired very little significance in human pathology.

At present, one was disposed to refer every abnormal constriction of vessels to excitation, and dilatation of the same to paralysis of the vasoconstrictors. An intimate relation evidently existed between vasomotor phenomena and the autonomic (sympathetic) nervous system. The blood supply of all parts was controlled by the vasomotor mechanism which regulated the amount of varying the caliber of arteries. The adaptability of the vascular system was wonderfully complete, and was worked out through the reflex activity of the nervous system exerted partly on the vasomotor fibers and partly upon the regulatory nerves of the heart. The center of control was influenced by various stimuli, central (cerebral), visceral and external. In health vasomotor reactions were not subject to great variations. The existence of an unknown and ill-defined instability of the vasomotor mechanism found expression in the abnormal states referred to as vasomotor disorders or trophoneuroses. The signs of imperfect vascular coordination were frequently associated with metabolic perversions as represented by gout, diabetes, and the different forms of arthritis. They were furthermore closely related to such conditions as migraine, urticaria, asthma, and hay fever. Inasmuch as signs of vasomotor instability very often did not permit of classifying as a definite vasomotor disorder, it seemed difficult to group them under one heading that would be sufficiently expressive of this condition. The term vasomotor ataxia was proposed by Solomon Solis-Cohen in 1885, which had subsequently been amplified to autonomic ataxia. Vasomotor ataxia was to represent a condition of the sympathetic nervous system through which, as a result of hereditary or debilitating influences it failed to carry on adequately its visceral and especially its cardiovascular functions. The vasomotor circulatory aberrations could be provoked under the incidence of various exciting causes, which might be constrictive, dilative, or a mixture of the two, and produced local, diffuse or general disturbances. In a similar way various types of secretory and viscero-motor disorders could be produced. As chief exciting influences might be mentioned, heat, cold, emotional influences as worry and shocki and toxic agents of endogenous or exogenous nature. The symptoms of this unclassified group were widespread, those pertaining to the peripheral circulation being readily observed. The changes in the skin were indicated by a peculiar cutaneous marbling, angio-neurotic congestion and edema, varices, which might be equally manifested on the different mucosae as the conjunctivae, lips, nares, larynx, cardia, pylorus, gall-bladder, and appendix. The subjective phenomena were usually paroxysmal, recurrent, or painful, appearing in the upper respiratory tract as paroxysms of hay fever and asthma; on the skin as urticaria, eczema, purpura and angioneurotic swellings. Painful spasms suggesting renal colic and appendicitis were encountered. Hematemesis might be a feature. Palpitation, tachycardia, leg cramps and variations in blood pressure were definite manifestations. The finger nails presented varying changes in color—pink, red, blue and leaden or mottled. The whole gamut of Graves' disease could be represented, as well as certain phenomena of Raynaud's disease, and thus symbolized the different conditions definitely classed as vasomotor disorders. A sensitiveness to drug reactions, anaphylactic phenomena and vasomotor paresis, in the different acute infectious diseases could properly be regarded as expressions of an unstable vasomotor mechanism. To illustrate the extent to which vasomotor phenomena might predominate in the clinical picture, the author related the histories of three cases.

Surgical Aspects of Pernicious Anemia.—Dr. W. D. GATCH of Indianapolis said that attempts to cure pernicious anemia by surgical methods had been made along three different lines: (1) Since it was generally supposed that a toxin was a factor in the causation of pernicious anemia, repeated attempts to cure the condition had been made by the removal of possible foci of infection or toxemia in the teeth, tonsils, gall-bladder, appendix, etc. (2) Since the spleen played a definite part in the causation of splenic anemia, as proved by the cure of this disease by splenectomy, this operation had been tried repeatedly as a means of treating pernicious anemia. (3) Since by the transfusion of blood any anemia could be removed, this procedure had come to be the standard treatment for all grave anemias. All three of these methods had frequently been combined in the treatment. That pernicious anemia was caused wholly by foci of chronic infection seemed to the writer highly improbable. Infection, acute or chronic, could, of course, cause a grave anemia; could even produce a blood picture in some respects like that seen in the pernicious type. But the anemia promptly cleared up on the removal of the infection, and the other clinical features of pernicious anemia were not present. Again pernicious anemia was a rather rare disease, while chronic infection was very common. Furthermore, cases of pernicious anemia did not invariably, even at autopsy, show foci of sepsis. In 20 cases of this disease treated at the Robert W. Long Hospital, 8 showed no evidence of such foci. One at autopsy showed gallstones and chronic cholecystitis, 9 had oral sepsis of greater or less degree—bad in three or four cases, one had had acute rheumatic fever, and one had chronic gonorrhea, tertiary syphilis, and had been subject to sore throat. It was generally admitted that splenectomy might produce a considerable improvement in the patient's condition, but it was likewise true that the improvement was only temporary. Splenectomy in pernicious anemia did not appear to be based on sound reasoning, and there seemed to be no foundation for the belief that splenectomy would cure pernicious anemia. Considering the confusion which so often attended the early diagnosis it seemed probable that obscure cases of hemolytic icterus and splenic anemia had been accidentally included in the pernicious anemia group. Removal of the spleen in such cases had given the impression that splenectomy cured pernicious anemia. In his experience in the cases in which the results were most favorable the symptoms were less characteristic of pernicious anemia. In the transfusion of blood one undoubtedly had a means of producing a great, though temporary, improvement in the patient's condition. But we should not expect too much of transfusion. It was commonly stated that blood from a donor belonging to Group IV could be used to transfuse a member of any other blood group. This was based upon the fact, established by experience, that serious results would not occur provided the cells of the donor were not agglutinated by the serum of the recipient. But it failed to consider that the serum of the donor might have a hemolytic action on the recipients' corpuscles. In pernicious anemia he believed that this action might partly, at least, prevent the good effects of the transfusion. For this reason he had always used donors belonging to the same blood group as the recipient. There was considerable literature on the subject of chills following blood transfusions. In over a hundred transfusions in which donor and recipient were of the same group, he had observed but one chill. Perhaps the occurrence of chills was to be in part explained by the hemolysis of the recipient's blood by the donor's serum. This idea was supported by the demonstration by Brown, of the Rockefeller Institute, that the chills in malaria were due to the hematin set free by the malarial parasites. The author's experience with a modification of the Kimpton-Brown method of transfusing whole blood had been so satisfactory that he had no hesitation in recommending it. His experience at the Long Hospital had been that the best results were obtained by transfusing enough blood to raise the hemoglobin reading to 70 per cent. or 80 per cent., 600 c.c. to 800 c.c. being given each time. After transfusions of the necessary amounts several patients who entered the hospital bedridden and lethargic had gone out and for periods of several weeks attended to their ordinary business. But none of the results had been lasting. The following were the speaker's conclusions: "(1) Pernicious anemia by present methods of treatment is an incurable disease. (2) Splenectomy may produce a temporary improvement in this disease, but in view of its dangers should not be done without careful consideration of all the factors involved. (3) The transfusion of whole blood from a donor belonging to the same blood group in large quantity, will produce great, though temporary, improvement in the patient's condition, but will not relieve all his symptoms."

Recent Advances in the Treatment of Epilepsy.—Dr. WILLIAM C. VAN NUYS of New Castle, Ind., said that in spite of the many theories, speculations and carefully studied symptomatology, one must agree with Coriat that "we are dealing with a disorder of unknown nature, periodic in type, although the exact origin of periodicity is not known, and manifesting itself sometimes as a motor disturbance, sometimes as a sensory reaction and sometimes as an interruption of consciousness." There was not even unanimity of opinion as to what convulsive phenomena should be included under the general terms, epilepsy. In the examination of a large series of cases, no two persons could agree on the idiopathic and smptomatic classifications. Inevitably, the drift was toward one of two conclusions, namely, that the differences were superficial and all convulsive phenomena had a common origin, or that there were many causes of convulsions that all epilepsies were symptomatic. L. Pierce Clark, after a study of a number of hemiplegic epileptics, found that they had about the same heredity and personality makeup as idiopathic epileptics. There was a grea diversity of opinion in regard to the relationship of convulsions in infancy and childhood to epilepsy in later life, but this might be said with certainty: Many epileptics had had convulsions in early life at the onset of acute febrile diseases, or during attacks of acute indigestion. When a child had reacted to any stress by having a convulsion, one was in possession of definite information in regard to that child. One knew that it was possible for that individual to have a convulsion. One could not say that such an infant or child would develop epilepsy, but one should be on their guard against it. Was it possible that from birth certain character traits were manifested by the individual who was later to become epileptic? This was important not only from the standpoint of establishing predisposition in epilepsy, for if it be shown to be true, treatment could be instituted against a threatened epilepsy and possibly frank manifestations of the disease could be prevented. Dr. L. Pierce Clark believed that certain peculiar character traits antedated the appearance of seizures and most frequently dated from birth. The peculiar character traits were supersensitiveness, egotism, emotional poverty, lack of power of adaptation. Many such individuals were self-assertive, shallow in their affections, indifferent to the rights of others. Dr. Clark referred to such individuals as "potential epileptics." It was not contended that all individuals who possessed this combination of traits, even in marked degree, would become epileptic, but that such a makeup was good soil for the development of frank epilepsy. Treatment must be based on understanding of the psychic and somatic makeup of the epileptic and recognition of the fact that he was a misfit in the home, the community and even in special institutions for his care. There must be, also, a clear conception of the object of treatment. Was the aim a cessation of seizures only? Obviously an individual with the characteristics enumerated above would be a misfit in the home and community even without epileptic seizures. The goal must be to so benefit the individual that he might be able to earn a living and react in a reasonably proper manner to the environment of home and community. This might be possible, in some cases, without an entire cessation of seizures. The epileptic should be acquainted with his character defects and encouraged to remedy them. Of equal importance was a life without physical or mental strain. As the individual had become epileptic in his present environment, a change was usually desirable. In many instances this would mean residence in a colony or special institution for epileptics. Few physicians in private practice had the time or inclination to give to these cases the minute attention to details necessary to secure results, and few patients were able to bear the financial burden of such attention. It should be taken for granted that before treatment was instituted the patient should undergo a most searching examination in regard to his family history, mode of living, habits, and reaction to his environment, in an effort to give proper recognition to the various factors that had led to his undoing. Co-operation of the patient must be secured and his relations with the physician must be friendly and confidential. The physical examination must be no less carefully made, including the routine laboratory tests. Paresis, dementia precox, multiple sclerosis, and syringomyelia could usually be excluded, although these cases were frequently committed to institutions for epileptics with a diagnosis of epilepsy. He had never seen a cessation of seizures following relief of eye strain or removal of diseased tonsils alone, but he firmly believed that careful attention to the teeth and proper medical surgical treatment of diseased and abnormal conditions of the eye, ear, nose, and throat had exerted a good influence in the treatment of many cases of epilepsy. Such examinations should be made as a routine and in the treatment of conditions disclosed by such examinations the patient should be given the benefit of the doubt. It was doubtful whether the prohibition of certain articles of diet of two decades ago was productive of real good in the treatment of epilepsy. The epileptic should eat slowly and sparingly. Alcohol was not for him. It might be said that bromides in certain cases, in correct dosage for those individual cases, would reduce the number of seizures or even cause a cessation of seizures for long periods. In many cases they did not have this effect. There could be no doubt that the careless, indiscriminate use of bromides had done great harm in epilepsy. Of late he had used luminal and luminal sodium rather extensively at the Indiana Village for Epileptics. At the present time about 200 patients were receiving this treatment, some having taken the drug daily for eight months. The dosage used was 1½ grains of luminal or 2 grains of luminal sodium at bed time each night.

The Prognosis of Dementia Precox.—Dr. EGBERT W. FELL of Cincinnati, O., said there was no doubt that the dementia precox group would eventually be split up and possibly there would be left in it only those cases that did not recover, but at present such a separation was not practical, for the reason that it was not possible during the course of the disease. Even when considered in this way, dementia precox was not a hopeful condition, but it was the belief of the writer that an absolutely pessimistic attitude was not justified. As the matter now stood the problem was to try to decide in an individual case showing the precox reaction whether or not there was likely to be a recovery. It was usually possible, though by no means always, fairly early in the course to say whether the hebephrenic, the catatonic, or the paranoid features would predominate. This being determined, he knew that the catatonics had the best chance of clearing, the hebephrenics the next, and the paranoids the least. In a given case he was inclined to feel more hopeful if the onset had been abrupt than if it had started insidiously. Unfortunately, it was impossible to tell from the intensity of the symptoms presented which case of hebephrenia or of catatonia would recover and which would go on to dementia. Two cases might have very similar clinical features, one deteriorate and the other make a partial or complete recovery. Many of the prison psychoses showed the precox type of reaction and subsided completely with a removal of the exciting cause, to reappear, perhaps, when that cause or one equally great was again met. Without entering into a discussion of the essential nature of dementia precox it seemed apparent that this type of reaction occurred only in persons of a particular makeup or personality which rendered them incapable of making a practical adjustment of their difficulties. This "shut-in" type of personality or tendency to avoid the realities of life, seemed to condition the development of the precox reaction and to preclude a manic reaction. This trait, while differing in degree in victims of dementia precox, could be shown almost invariably to have been present. The second variable factor in the development of the psychosis was the difficulty met with, or the exciting cause. In some the taint or predisposition amove mentioned, the physical as well as the mental stigmata were so pronounced as to indicate that he was only endowed with sufficient energy to carry him a short distance; that at about the age of puberty he had reached his limit, and began to go backward. In the majority, though, an additional definite stress was necessary. This might be a purely psychic shock, a psychic shock with accompanying physical hardships, a traumatism, or an infection. Just how these agencies worked did not concern us especially at the present

time. It might be by a direct effect on the nervous tissue, by the formation of endogenous or exogenous toxins, or only secondarily affecting the brain cells through the endocrine glands; but of this much one could be reasonably sure, there must first be the necessary groundwork and then an exciting cause. A precox episode coming on without apparent adequate cause in one who had the underlying personality strongly marked, was not so likely to make an adjustment as was one in an individual who developed the same type of reaction only when subjected to some great stress such as war, childbirth, or influenza. These observations had a practical importance in the prognosis of dementia precox in calling attention to the fact that psychoses of the dementia precox type did recover more often than one would be inclined to think when the diagnosis of dementia precox was made. Patients showing the precox type of reaction did at times recover. Examples of such were seen following influenza, during the puerperium, and in the dementia precox seen in the war. Calling the case that recovered by some other name merely because they did make an adjustment was of no help in prognosis, since there was nothing in the symptoms presented to show which would and which would not recover. A consideration of the makeup of the individual and of the exciting stress, would be of help in giving a prognosis. The less he was predisposed by personality and the greater the exciting stress, the more likely was an adjustment to take place, provided the stress was removed and proper treatment instituted.

The Primary Anemias; Pathological Consideration.—Dr. VIRGIL H. MOON of Indianapolis said that the term "primary anemias" had been applied to that group of anemias for which no cause had been shown, and which had been thought by some to originate primarily in the blood as the term implied. Commonly grouped under this heading were chlorosis, hemolytic icterus, splenic anemia, or Banti's disease, pernicious anemia, and aplastic anemia. These conditions were sharply different and had but two points of similarity in common, to wit: impoverishment of blood and unknown etiology. It was evident then that the only justification for the term "primary anemia" as here applied lay in the fact that the etiology was unknown. No one held the opinion that the cause of any two of these was identical, and should the cause of any one of them be demonstrated that one would immediately be taken out of this group. The term "primary anemia" was unfortunate and its use should be discouraged. The pathological changes associated with pernicious anemia might be considered in two groups. In the first would be considered those changes due directly to the anemia. These changes were essentially due to the decreased oxygen carrying capacity of the blood. Decreased oxidation resulted in accumulation of the fats and carbohydrates brought in as food. Not only were the normal reservoirs of fat about the body not depleted, but the fat which was brought to the liver, heart, and kidney cells accumulated, producing marked fatty infiltration of the cells of those organs. It should be noted at this point that some authors ascribed these fatty changes to cellular degeneration produced by the unknown poison which was assumed to cause the anemia. The decreased oxygen-carrying capacity of the blood was made evident physiologically in the shortness of breath on exertion which was a prominent feature clinically in this condition. The digestion in most cases was not seriously impaired, and the body was surprisingly well nourished. This fact invited the explanation that the blood plasma was not greatly impoverished, and hence that the nourishing power of the blood was not greatly impaired. In this particular then there was a very definite difference from the cachectic anemias in which there was impoverishment of both plasma and corpuscles, and in which therefore both the nourishing and the oxygen-carrying function of the blood were greatly impaired. The second group of changes consisted of those not referable to the anemia itself, but which were ascribed to the action of the toxic agent which produced the anemia. The body, as a whole, was not emaciated, and at times there was an excess of adipose tissue. The skeletal muscles were bright red, but the organs of the body were much paler than normally and usually showed a yellowish or brownish pigmentation. Frequently there were hemorrhages in the serous surfaces and effusions into the serous cavities. Brownish patches resulting from hemorrhages were found often on the dorsal surface of the tongue. Frequently also there were ulcers about the base of the tongue which Hunter regarded as characteristic of pernicious anemia, and believed to be the portals of entry for the bacteria which he assumed produced the anemia. The heart was often moderately enlarged, and there was moderate widening of the mitral ring. The heart musculature was characterized by marked fatty changes which gave it a speckled or striped appearance grossly. Pigmentation was usually present, and there might be small epicardial or endocardial hemorrhages. The liver was enlarged and distinctly yellow in color. There was marked fatty infiltration in the central zone of the liver lobules. Blood destruction was evidenced by the presence of quantities of iron-containing pigment deposited here. The same occurred also in the kidney cortex, the lymph nodes and spleen. The spleen was usually small, showing a form of atrophy characterized by severe cellular poverty. This was in contrast to the hyperplasia and marked regenerative activity present in the bone marrow. The phagocytes of the spleen contained masses of brown pigment derived from the destruction of hemoglobin. They also contained numerous red cells in varying stages of disintegration. Most marked changes occurred in the cord. These consisted of focal areas of degeneration of the nerve fibers, especially in the posterior columns, but frequently scattered among the other tracts. These produced irregular ascending degeneration accompanied by sensory disturbances, sometimes ataxic phenomena resembling tabes very closely. Such changes were not explicable as due to anemia alone. The tissues suggested the action of some powerful poison evidenced in the blood by hemolysis, evidenced in the cord by systemic or by patchy degeneration, and evidenced in the cells of the parenchymatous organs by marked degeneration. That the blood was not the primary seat of the injury was shown by the fact that in some cases the spinal cord showed earlier and more marked changes than did the blood.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Nov. 4, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was arranged by Dr. William Hallock Park of the Bureau of Laboratories, Department of Health.

The Bacteriology of the Acute Respiratory Infections, Not Including the Pneumonias.—Dr. ANNA W. WILLIAMS made this presentation which consisted of a report of some of the results of an investigation carried out in conjunction with the Metropolitan Life Insurance Company concerning the causes of common colds and of pandemic influenza. Among the difficulties of conducting such a bacteriological investigation were: (1) the selection of suitable media; (2) the finding of an area of infection where one would be able to obtain sufficient material at the right stages of the disease. This investigation was started before the last wave of influenza with an attempt to get the pre-disease bacterial curve in a group of individuals, but the wave of influenza came and they then decided to search for a dominant strain among the groups of bacteria that others had laimed were implicated in the cause of the pandemic. In their study of this part of the work they had employed four media—vitamine, oleate, blood drop, and blood pour. Each of these was especially good for different types of microorganisms. The microorganisms found were divided into four groups: (1) Gram positive cocci; (2) Gram negative cocci; (3) influenza bacilli, and (4) other bacteria. Dr. Williams exhibited a chart which showed the incidence of the different groups of organisms taken from the nasopharynx and grown on these different media. The chart showed also the bacterial curve in normal individuals and in a number of abnormal cases; and the comparison between a normal case and a typical case of influenza. In the normal cases each presented a different picture from

the others. One kind of microorganisms predominated though it differed in kind in different individuals. On the whole different kinds of Gram-positive cocci predominated but Gram-negative cocci were also frequent and comparatively abundant. Influenza bacilli were very infrequent, and other microorganisms were in abundance irregularly. In *acute rhinitis* where most of the cultures were taken very early in the disease, the picture did not differ much as a whole from the normals, neither did the first cases of *pharyngitis* though actually in both these groups, individual cases seemed to be due, judging from the majority, to one type of organism different in different individuals, but in the cases examined nearer the time of the epidemic, the picture was more like that of the "flu" cases. In the "flu" cases which gave a common chart on the average, there was a marked jump in the influenza bacilli and in a special colony type of the Gram-positive cocci (minute green). There was a drop in the Gram-negative cocci, and there was a great increase in the number of *minute delicate* colonies, grouped mostly with "others" on vitamine media. In hunting for a dominant strain, ten or more colonies in any one cases that seemed alike were fished out and subjected to further study. During the pandemic they had concentrated on the influenza bacilli, but they found practically no strain which they considered gave strong enough evidence to warrant the conclusion that it was the cause of the pandemic, and they were forced to the conclusion that the influenza bacillus had nothing to do with the pandemic primarily. The other type of organisms predominating in influenza, those producing small colonies on blood agar with a halo of green, had been studied during last winter's wave of influenza in the same way as were the influenza bacillus fishings during the pandemic, and the evidence so far showed no predominating organism among them. Pneumococci and hemolytic streptococci while not predominating in these cases were also studied in the same way with similar results. Thus this work so far seemed to rule out as the primary cause of influenza the hemolytic streptococci, the pneumococci and other "green producing streptococci," the Gram negative cocci group and the influenza bacillus, while in common colds different members of these groups might be the primary cause. This left open the question of the etiological relationships to influenza of certain delicately growing organisms not showing a majority incidence by their methods, of anaerobic organisms, and of filtrable organisms. It also helped explain why their vaccines had not had a more specific effect.

Report of the Prophylactic Vaccination of 1536 Persons Against Acute Respiratory Diseases, 1919-1920.—Dr. ANNA I. VON SHOLLY and Dr. WILLIAM H. PARK contributed this paper which was read by Dr. Von Sholly. They stated that the reason for the investigation upon which this report was based was an attempt to clear up, if possible, the status of a vaccine made of mixed organisms which predominated in respiratory diseases, as a prophylactic agent in epidemic "grippe" and acute respiratory diseases in general. Briefly, their aim was to inoculate prophylactically a group of people well in advance of any anticipated recurrence of epidemic grippe, so that whatever immunity might be stimulated by the method would be already established before exposure to the disease. Moreover, they wished to learn what effect a vaccine made of the predominant organisms of the acute respiratory diseases would have in inhibiting or modifying these diseases. They aimed to have for comparison an uninoculated control group as similar as possible to the group inoculated. The work presented was done between September 30, 1919, and April 3, 1920, among the general employees of the Metropolitan Life Insurance Company's home Office, New York City, under the direction of the Research Laboratory of the New York City Health Department, co-operating with the officers of the Metropolitan Life Insurance Company. The groups under observation consisted of men and women, all volunteers, of varying ages. In all, there were 1,536 people who were inoculated, of whom 1,293 received three inoculations, 95 two inoculations, and 148 only one inoculation. As a control group 3,020 persons of similar ages and both sexes of the same company were under continuous observation. A comparison of 1,500 histories taken at random showed similarity between the inoculated and uninoculated groups. The very careful method of following up these groups was described. The inoculations were given at weekly intervals during the end of September, 1919, and the first three weeks of October, 1919. Two vaccines were used. The larger group of people, numbering 1,412, were given Vaccine L, which was a saline suspension sterilized by heat, containing 1,000 million per c.c. each of the *B. influenzæ, Streptococcus hemolyticus,* and *Streptococcus viridans;* 2,000 millions each of pneumococcus, type I and type II, and 1,000 million pneumococcus, type III, per c.c. The smaller group, numbering 124, were given Vaccine R, a vaccine similar in composition to that given by Rosenow of the Mayo Clinic. A careful record of reactions to the vaccines was kept, partly for general scientific knowledge and partly for the purpose of finding out the practicability of group vaccination for a commercial company from the point of view of loss of services following and due to the inoculations. The injections were given subcutaneously in the deltoid region. The first dose was ½ c.c., and the second and third were one c.c. each. Detailed figures in regard to the local and general reactions showed that the largest number of reactions, as was to be anticipated, followed the second injection and that the severe reactions were comparatively few. There were no really alarming reactions. That some persons should take advantage of the inoculations to remain at home would not be at all surprising, but giving everybody the benefit of the doubt and counting all absences immediately following vaccination as due to it, there were, in all, 87 persons who were absent from work anywhere from a half day to twenty-four days. The total days' absence of this group was 181½ days, or 2 days and 42 minutes for each one. The average absence per person for the total inoculated group, 1,536 persons, taking the working day as eight hours, was about 56 minutes. Comparing these percentages with the absences due to respiratory diseases during the six months' observation period, it was found that the uninoculated lost 8,172 days, or an average of 2.2 days per person during the same interval. If the average of the inoculated persons' absence due to respiratory disease were added to the average absence credited to the inoculations, there was still a gain of a good half working day per person in favor of the inoculated. It was fair to assume that if the custom of annual vaccinations were established absences due to inoculation would diminish. A tabulation was made to learn if there was any demonstrable relationship between past respiratory diseases, such as pneumonia, bronchitis, grippe, etc., and the character and severity of the reactions from the inoculations. No special susceptibility to vaccines could be established for these diseases. In studying the respiratory affections occurring in these groups during this six months' period, there were 1,297 completed records of inoculated persons under continuous observation during the above period, and 3,020 similar records of the uninoculated. Among the inoculated, 19.4 per cent. gave a history of no respiratory affections during this time. Among the non-inoculated, 37.7 per cent. gave a similar history. Detailed records of the incidence of upper and lower respiratory affections were analyzed from which it seemed fair to conclude that the kind of vaccine used, in the manner and dosage used by the authors, had very little specific influence either in preventing or causing respiratory disease other than pneumonia. The difference in pneumonia, however, was marked between the two groups. The inoculated showed one case against 11 cases among the non-inoculated. Although it might be an accidental situation, it would seem fair to make some claims for the efficacy of a typed pneumo-streptococcus vaccine for pneumonia. The one case of pneumonia which occurred in the inoculated group was in a girl who had had only one injection of the vaccine. She suffered from influenza and bronchopneumonia more than five months after vaccination. Lister of South Africa did not claim much immunity for his pneumococcus vaccine for more than four to six months. After the investigation was closed, two more cases of pneumonia were reported among the inoculated. Both occurred about seven months after the vaccination.

One of the most important phases of the investigation was the completion of the vaccinations about three months before the brief flare-up of grippe in January, 1920. A comparison of the inoculated and uninoculated groups showed very little difference in their respective degrees of immunity to pandemic grippe. Most of the grippe cases of 1920 were comparatively mild. The inoculated averaged 7.2 days absence per person, and the non-inoculated averaged 9.2 days per person. This difference could be only to a slight degree accounted for by the fact that the pneumonias occurred more frequently among the uninoculated. In concluding, the writers expressed the opinion that contrary opinions might be drawn depending upon what part of the report one laid the more stress. If we compared the incidence of the respiratory affections among the inoculated and the uninoculated, excluding pneumonia, and the severity of these affections, we might assert that the vaccines were of little or no appreciable value. If, on the other hand, we focused our attention on the figures that showed a somewhat higher susceptibility to respiratory diseases among the vaccinated in their past histories, a larger group absence for respiratory disease among the non-vaccinated, and a longer absence per person for attacks of grippe in the non-inoculated group, we might conclude that the vaccines had a beneficial influence. On the whole, balancing both sides, the evidence did not make a strong case in favor of the vaccines given by them as a prophylactic agent against acute respiratory diseases, pneumonia alone excepted. Their work tended to confirm the conclusions of Lister and Cecil and Austin on the typed pneumococcus vaccine for pneumonia. It pointed to the importance of further research along this line.

Influenza Meningitis.—Dr. JOSEPHINE B. NEAL read this paper in which she stated that although a fairly large number of cases of influenza meningitis had been reported, the disease was far from common, ranking fourth in their experience, in the types of purulent meningitis. Charts were exhibited showing the incidence of the different forms of purulent meningitis among the cases of meningeal involvements studied by the meningitis division during the past ten years and also showing the cases collected and reported by various workers. In their series of 32 cases the diagnosis was made by finding in the spinal fluid the Gram negative hemoglobinophilic bacillus, described by Pfeiffer. In smears from the spinal fluid these bacilli showed a high degree of plenomorphism, a fact observed by several other workers. An interesting point was brought out by Dr. Povisky of the Research Laboratory, who found that four out of seven strains from cases of influenza meningitis belonged to the same type by agglutination, whereas the strains isolated from the respiratory tract during the epidemic of influenza so-called, and studied by her and her co-workers, showed only a slight tendency to fall into groups. It was only by the bacteriological study of the spinal fluid that the diagnosis of influenzal meningitis could be made during life, and there was nothing in the history or clinical picture of the case, or in other characteristics of the spinal fluid to distinguish it from other forms of purulent meningitis. Indeed, from the clinical standpoint it was especially liable to escape diagnosis, since so large a proportion of the cases were in infants, in whom the diagnosis of meningitis was difficult to make. It was evidently a disease of young children, 30 of their 32 cases being under five years of age. They were able to locate a probable primary focus in only 8 instances, six being pneumonia, one clinical influenza, and one a cold and cough. It was certain that meningitis due to the meningococcus developed not infrequently during or immediately following pneumonia, and lumbar puncture was all too often delayed because the physician felt he was dealing with a meningism or with a meningitis secondary to pneumonia, probably due to the pneumococcus or streptococcus. There seemed to be a tendency for the cases to develop in the fall and early winter. It was of particular interest to note that in the fall of 1918 when the epidemic of influenza was raging in New York City they saw only one case of meningitis due to the Pfeiffer bacillus. This seemed good evidence against the Pfeiffer bacillus being the causative factor of this epidemic. The course of the disease varied greatly—from two or three days to a month or more. It was usually well over a week. A study of 12 cases in which recovery took place showed that in 8 instances lumbar puncture alone was used. In one instance electrargol was given intravenously for a week; in two cases anti-influenzal serum was used, and in one vaccine intraspinally. They had used the Wollstein anti-influenzal serum in five cases, in three of which only one or two injections were given, and in two the injections were repeated about ten times in one and fifteen in the other. These last two cases showed temporary improvement clinically and the organisms decreased greatly in number and became largely intracellular, but death finally resulted. This serum should certainly be used when available. Dr. Neal related the history of one case of influenzal meningitis which recovered under a combination stock and autogenous of anti-influenzal serum and vaccines. In several cases of meningitis not due to the meningococcus a vaccine was used intraspinally hoping that its gradual absorption into the blood stream would give whatever beneficial effects resulted from the vaccine given intravenously without the degree of shock usually following that method of administration. One case of staphylococcus meningitis recovered and there was temporary improvement in three others, following intraspinal treatment. The reaction from this treatment had never been very severe and there had apparently been no harmful results, though in some cases Dr. Neal said she had worked up to a dose as large as five billion diluted in about 10 c.c. of saline solution. The vaccines used were either stock vaccines of the same strain as the organism present or autogenous vaccines when such could be prepared. Vaccines had also been used intravenously to a limited extent in treating meningitis, in which they caused considerable shock. Recoveries from purulent meningitis not due to the meningococcus were few. Most of them had occurred after lumbar puncture alone. In view of this fact, Dr. Neal said she wished to make it clear that she did not claim that intraspinal vaccine treatment cured these two cases of staphylococcus and influenzal meningitis which she had described or that the intravenous administration of vaccine cured two cases of blocked meningitis to which she referred. However, recovery did follow its use. In the absence of any more encouraging form of treatment, it seemed worth while trying intraspinal or intravenous administration of vaccines as the condition indicated in addition to an homologous serum, if such were available in cases of purulent meningitis not due to the meningococcus, and in blocked forms of epidemic meningitis.

Dr. HENRY KOPLIK expressed admiration for Dr. Neal's paper on influenzal meningitis. He said he had regarded this form of meningitis as very fatal. He had tried to make an early diagnosis of this type of meningitis and to treat it with injections of Dr. Wollstein's serum, but in all cases so treated had not been successful. Whether this was due to the fact that he did not get the cases early enough he could not say. Repeated injections of the serum were of no avail. However, cases were reported, particularly from Germany, in which recovery occurred following repeated lumbar puncture before the advent of Wollstein's serum. With some strains of the influenza bacillus children recovered if repeated lumbar punctures were made. He had had one case before Dr. Wollstein's serum was brought out which recovered with repeated lumbar punctures. That case was very carefully investigated in the hospital laboratory. These forms of influenza meningitis were virulent as were those of pneumococcus meningitis. This was shown by the fact that of the 158 cases reported in the paper only 12 recovered. These statistics were exceedingly useful and very instructive.

Dr. RUSSELL L. CECIL said he was particularly interested in the paper of Dr. Von Sholly and Dr. Park in view of the work he had done in the army with pneumococcus vaccine as a prophylactic against pneumonia. As to the common colds, the conclusions of Dr. Von Sholly and Dr. Park corroborated those of other observers who had had experience with the stock vaccines. The general consensus of opinion was that shotgun vaccines offered no protection against common colds. It was possible, however, that autogenous vaccine

might be of benefit in individual cases, where the patient was sensitive to some particular organism. Dr. Cecil said he had seen several instances of this kind in children who gave pure cultures of the streptococcus or pneumococcus and in whom autogenous vaccines had prevented future attacks. It was gratifying to learn of the favorable experience of the authors with the vaccine againt pneumonia. In his work he had had encouraging results with a triple vaccine containing pneumococci of types I, II and III. He was sorry Dr. Von Sholly had not told them something about the types of pneumonia developing among the vaccinated, for possibly the types of pneumonia that developed were those not included in the vaccine. The experience with influenza described in the paper corresponded with his work at Camp Wheeler, where they found that pneumococcus vaccine had no effect on the incidence of influenza. They did think, however, that these vaccines had had some effect in decreasing the death rate from pneumonia. Though the incidence of pneumonia was just as high, they thought that the mortality rate was somewhat lowered.

Dr. WOLFF FREUDENTHAL said that Dr. Williams and Dr. Von Sholly had told them a great deal about the organisms found in common colds. If they had only told him what a common cold was he would be a great deal happier. Acute rhinitis had to be differentiated into several classes. One class was decidedly infectious, and another was due to exposure. In the first class one might find some serum or vaccine which would give favorable results, but such treatment in the other class would give 100 per cent. of disappointing results. Then there were different forms of rhinitis which were not of the acute variety; for instance, certain atrophic conditions in which crusts were formed and these might at times give the appearance of a "common cold" by causing an irritation. Here again in this class of cases one could expect no help from vaccines.

Dr. EDWARD S. MCSWEENY spoke briefly of a work similar to that described by Dr. Von Sholly which was being carried on by the New York Telephone Company working in conjunction with the Health Department. While he did not have detailed statistics with him, he stated that the number of cases treated was about 1,500, and something over 1,000 of these received the full series of inoculations. In that group, one pneumonia developed. The incidence of pneumonia in the group, therefore, was something less than one per thousand, while among the non-inoculated controls, 5.5 per thousand occurred, which was quite in keeping with the results reported this evening. These figures were not open to question, but the figures in connection with colds presented quite a different situation. He had made the attempt to get figures on colds, but had abandoned it, because of the apparent hopelessness of determining when people had colds. One had to depend to a great extent on the statements of the patients, and the patient was open to so much self-suggestion, that any figures on the result of vaccines in the prevention of colds were open to question. However, about two-thirds of those inoculated claimed an improvement as to the number and severity of their colds over their previous experience. Whether they really were improved or not he could not say, but he would say that with the use of vaccines in a large series of cases one had a chance of about two to one of having a well satisfied patient.

The Results of the Use of Toxin-Antitoxin in Immunization Against Diphtheria During a Period of Six Years.—Drs. W. H. PARK, A. ZINGHER, and M. C. SCHROEDER presented this subject.

Dr. PARK explained that the subject of immunization against diphtheria was placed on the program because the Health Department was making an active drive to popularize this method of preventing diphtheria, and also because tests had been completed at the end of five years in some of the institutions in which immunization had been consistently carried on. The work of the Health Department in this line was being carried on under the direction of a committee which was appointed by Dr. Copeland. This was composed of Doctors Harris, Baker, and Park. Drs. Zingher and Schroder acting for the laboratory were the consultants to the Division of Child Hygiene and Preventable Diseases, and had the immediate direction of the work. The necessity for using active immunization became apparent when it was discovered several years ago that the gains made through antitoxin had come to a standstill. Through the use of antitoxin in immunization and treatment, the deaths had been decreased eighty per cent., but the cases only twenty-five per cent. This was true not only in New York but throughout the United States. Immunization with antitoxin was absolutely efficient for a brief space of time but ceased to give immunity after from two to four weeks. The Schick test became a very valuable aid in the use of the diphtheria vaccine, for when carefully carried out, it showed whether children had or did not have antitoxin. The vaccine could then be given to those in whom antitoxin was absent. Their investigations had shown that active immunization was successful at the end of three months in about 70 per cent. of those individuals giving a positive Schick test. At the end of a year active immunization was successful in about 92 per cent of those giving a positive Schick. Active immunization was particularly applicable to infants above six months and to children in the public schools, orphan asylums and other institutions. They had records of the children for from four to five years in some ten institutions. In two institutions it was found that at the end of a year from 92 to 98 per cent. of the non-immune became immune through the use of the toxin antitoxin mixtures. Subsequent tests made over a period of five years showed that instead of this immunity lessening, it had continued in all and it was justifiable to hope that it would hold for an indefinite period. It was probably true that not only did the toxin-antitoxin stimulate the production of antitoxin but that the cells once stimulated went on producing antitoxin. *The reliability of a negative Schick Test:*—Of 310 children in one home who were originally negative to the Schick test 94 had remained under observation and had been tested yearly. Of these five had become positive at some time. This might be explained on the ground that the children had been confused or because of some slight error in making the outfits a weaker toxin might have been used in making these tests. Whatever the cause they had to assume that with very careful workers there would be an annual change in the Schick reaction in 2 per cent. of the cases. The question might be raised whether we could trust a negative Schick reaction as proof of natural immunity. In their combined experience they had no record of an individual giving a negative Schick reaction contracting undoubted clinical diphtheria. A few such cases had been reported, but in most of these at least he felt quite sure the children did not have diphtheria. Certainly if diphtheria did sometimes occur it was simply a local condition. An interesting fact in connection with the production of active immunity was that the younger the child the less likely was it to suffer annoyance from the vaccination because of the proteins. The reaction when it occurred was not due to the neutralized toxins but to the injections of the peptone and bacillus protoplasm. It was found that in some 2,000 babies of three days of age, there resulted no harm from the injections but unfortunately at that early age there was no immunity produced. It was found that from the age of three months on infants could be immunized with success. From the age of three to eighteen months babies lost the mother's immunity. The earlier the child was immunized after reaching the age of six months, the greater would be the protection of that child. At the present time they were aiming to immunize the children in the schools, not only for the purpose of preventing deaths and diseases among them from diphtheria, but to increase and disseminate knowledge on this subject through the schools so that it would reach the homes and younger children could be protected. Dr. Park believed that when physicians were fully accustomed to the idea of active immunity against diphtheria they would lend their hearty cooperation to plans for the immunization of all children susceptible to diphtheria. Unless private physicians would undertake to do the injections themselves there was little hope of obtaining a marked diminution in diphtheria.

Between the ages of six months and two years the toxin-antitoxin was frequently given without having made a previous Schick test. There were two reasons for this. Children frequently kept their mother's antitoxin up to the end of the second year. In these a negative Schick did not give any security that a permanent natural immunity had developed. The other reason was the very slight reaction following the injection in infants.

Dr. A. ZINGHER, in speaking of the technique and reactions of the Schick test, said that three points were absolutely essential if the test was to be reliable: (1) A standard toxin dilution of proper strength. (2) Accurate technique in the injection by means of a good syringe and a suitable fine needle. (3) An accurate interpretation of the results. Schick test outfits were now being made by a number of manufacturers, but in using these commercial preparations one had to be very careful that he was getting a toxin of proper strength. The outfits for making the Schick test furnished by the Research Laboratory had given practically uniform results clinically, and the animal tests showed full potency of the toxin, hence they felt convinced that it was possible to manufacture outfits for the Schick test on a large scale without sacrificing accuracy. The technique was easily acquired but it was important that it should be carried out in a proper way. One should use a fine platinum or iridium needle and a 1 c.c. Record syringe. The fluid should be injected intradermically, giving 0.2 c.c. of the toxin. It was also important that the test be properly interpreted. If the child had antitoxin the reaction would be negative, that was the skin at the site of the injection would remain normal. A positive reaction was indicated by redness appearing within twenty-four to forty-eight hours after the injection, and a distinct reaction in from twenty-four to forty-eight hours. The reaction reached its height on the fourth day. Children under five years of age gave a very distinct positive or negative reaction, but older children and adults might give a pseudo reaction, which represented a local anaphylactic response of the tissue cells to the protein substance of the autolyzed diphtheria bacilli which was present in the toxin used for the test. This pseudo reaction reached its height within twenty-four hours and disappeared sooner than the true reaction, usually on the third or fourth day, leaving a poorly defined area of brownish pigmentation. In order to control the pseudo reaction the toxin might he heated to 75° C. for ten minutes for the purpose of destroying the soluble protein. A combined pseudo and true reaction represented a lack of immunity to diphtheria. In adults 30 to 40 per cent. gave a pseudo reaction, while only 10 to 15 per cent. gave a true positive reaction. The observations of the Health Department had shown that the Schick test and active immunization had been of immense value in controlling epidemic of diphtheria in institutions. Most striking have been the results noted at the Willard Parker Hospital, where more than 2,200 scarlet fever patients giving a negative Schick reaction on entering the institution, and no prophylactic injection of an antitoxin was given these patients, as they were considered immune to diphtheria. They were carefully observed and not one developed undoubted clinical diphtheria, even though they were subsequently exposed to diphtheria developing among some of the Schick positive patients; indeed, many of these had become temporary carriers of virulent diphtheria bacilli during their stay in the hospital.

Dr. M. C. SCHROEDER described the methods which she was employing in introducing the Schick test and toxin antitoxin immunization into the public schools. Having first gained permission to visit the schools for this purpose she took with her what she called the prize packages. These were two envelopes containing all the forms used in doing the Schick test in the infant health stations and institutions. These were given to the principal and assistant principal. For the teachers there were several different types of circulars. One of these was a plea to physicians; a second described what the Schick test was; a third described what immunization by toxin antitoxin meant to the children. Stress was laid on the following facts: First, the need of the work, the number of cases of diphtheria occurring in New York and the number of deaths from diphtheria; next, showing how they could be decreased. Then there were some figures on the incidence of diphtheria throughout the entire country and a brief history of the discovery of the diphtheria bacillus and the methods of making antitoxin and toxin antitoxin. The facts that no harm could result from the test and how much it protected against diphtheria were emphasized. As a rule they found the principals and teachers very willing to lend their cooperation. A short talk on the subject was given by the principal to the teachers and children in Assembly, and the teachers translated this into simpler language for the children in their class rooms. The children took home information to the mothers and fathers. Lectures on the subject were arranged for before the mothers' clubs, teachers' meetings and parents' associations. Finally, when the ground was prepared they asked how many circulars would be wanted, and these were printed in English, Yiddish, and Italian in order that those children might not suffer whose parents could not read English. The children then took home cards to be signed giving permission for the Schick test, for no child was given the test without a signed permit from its parents. On the day of the test the teacher was asked to collect the consents and to send them down to the test room. They tried to have a room with two doors so that the children could enter by one and leave by the other. The cards were called for and stamped with the current day on which the test was made. A specially sterilized needle was used for each child. The cards were kept until the day of reading, when the children again came in line and the reactions were read by a technician. The children showing a negative Schick reaction were turned back, and those showing a positive reaction were sent to an assistant technician and an immunizing dose of toxin antitoxin administered. The injection was given on the outside of the arm above the elbow. Formerly the site of the injection was swabbed with alcohol when that substance was plentiful. Now they were using soap and water and applying iodine. A second application of iodine was a part of the routine. They always had at hand aromatic spirit of ammonia, because if one child felt faint immediately a half dozen followed suit. They had very few swollen arms, and none that amounted to much. As the parents were learning the value of the Schick test and immunization they were bringing younger children so that she felt that there would be very little trouble in having the active toxin-antitoxin immunity test introduced into the schools as routine procedure.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE ORGANIC EFFECTS OF REPEATED BODILY ROTATION. By COLEMAN R. GRIFFITH. 125 pages with illustrations. Reprinted from *Journal of Experimental Psychology.*

A TEXT-BOOK OF HISTOLOGY. By FREDERICK R. BAILEY, M.D. 733 pages with illustrations. Published by William Wood & Company, New York.

A PRACTICAL MEDICAL DICTIONARY. By THOMAS LATHROP STEDMAN, M.D. 1144 pages with illustrations. Published by William Wood & Company, New York.

OXFORD MEDICINE. Edited by HENRY A. CHRISTIAN, M.D., and Sir JAMES MACKENZIE. 817 pages with illustrations. Vol. II. Published by the Oxford University Press, New York.

BACKWATERS OF LETHE. By G. A. H. BARTON, M.D. 151 pages with illustrations. Published by Paul B. Hoeber, New York.

PHARMACOLOGY. By DOUGLAS COW, M.D. 132 pages with 15 illustrations. Published by J. & A. Churchill, London.

Miscellany.

X-ray Finger Printing.—If the sulci in the finger tips are filled with some opaque substance of high atomic weight such as bismuth subcarbonate, the radiograph of the finger will show the whole pattern as distinctly as an ordinary finger print. If the same opaque substance is used to fill the groove about the nail this outline is superadded and the phalanges are, of course, strongly shown—a fact which suggests blunting the pattern of the finger ridges to some extent, although Béclère, who devised the method, assures us that this difficulty is not present in practice. The technique of obtaining the radiograms is given in detail. The method is not intended to displace ordinary Bertillon finger printing, but supplements the latter in several respects, such, for example, as in the drowned, when the Bertillon method falls short. There are other conditions, presumably in connection with occupations which tend to wear away the digital ridges—such as incessant handling of moving picture film—in which the added information of the ungual groove might have a decisive value. The radiograms are magnified and this, too, gives some advantage, although finger prints are magnified with the lens and may be reproduced in enlarged fashion. Stereoscopic radiography is still another resource of the new method which serves to bring out details, and by using a Coolidge tube a beautiful definition of the finger grooves is obtained. The article by Béclère, in the *Journal de Radiologie et d'Electrologie,* is abstracted in *La Presse Médicale* for August 28, 1920, xxviii, 61.

The Midwives and Woman Practitioners of Medicine in Ancient and Medieval Rome.—Raulin, who recently wrote an article on the earliest known medical practitioners of ancient Italy (abstracted at the time in the MEDICAL RECORD) has published a second article with the above title in the *Gazette hebdomadaire des sciences médicales de Bordeaux* for September 5, 1920, xli, 36. Midwifery is a very ancient profession, originally monopolized by women, and midwives even abound in mythology, various deities presiding over the individual steps in delivery. The scissors for cutting the cord were attributed to divine origin. Juno, or rather Hera, Ilythia, was the Greek goddess of childbirth and numerous sanctuaries were built in Greece for the cult which was introduced into Italy even before the arrival of the Etruscans. The name of the goddess was changed to Lucina, who, under this or other names, had her sanctuaries and feasts in Italy. Many women followed the cult and from these was evolved in time the Corporation of Midwives. It was but a step further to obstetrics as a whole and gynecology, and thence to general medicine. Our women physicians of to-day were therefore anticipated by many centuries. But many of these Roman women, it is to be feared, practised abortion, sorcery, fortune telling, and other devious vocations and in general were ignorant, audacious, and unscrupulous. They persisted from early times through the Republic and into the Empire and to the original personnel many female slaves or ex-slaves seem to have been added. Some bore the title *iatromea,* equivalent to midwife; others that of *medica* or woman physician. The names of many of them have come down to us through epitaphs. At the downfall of the Empire the female physicians went out of business but the midwives continued to flourish. Trotula de Ruggiere was famous in the eleventh century as the author of a treatise on childbirth. After her there was Rebecca Guarana, whose medical writings have perished; and in 1321 Françoise de Romana was licensed to practise surgery. Others received degrees from the School of Salernum (*matronæ salernitanæ*) down to the later years of the eighteenth century.

American Settlement House in Paris Slums.—In 1917 the American Red Cross established a model settlement house, the Nineteenth Ward Social Center, in the heart of the Paris slums, where for years the average child mortality has been between 30 and 40 per cent. Of 1,127 nursing infants treated at the Red Cross foundation during a period of ten months, only 39 died, whereas, under ordinary circumstances, 394 of these children would have succumbed. The total mortality among the children cared for by the institution has been 3 per cent., as against 40 per cent. for the other children of the same district. This settlement house has been adopted by the French as a model for the future organization of all medico-social service in France. This is said to be the first time that France has seen a practical demonstration of American medico-social methods. Between the months of July, 1919, and May, 1920, the Social Center of the Nineteenth Ward provided 462 medical clinics for its charges. These clinics were attended by 9,016 mothers and children. The institution's social workers and nurses made 16,160 home visits and inspections during this period.

Monument to Lannelongue.—This well-known French surgeon died in 1911 and the movement to honor his memory was interrupted by the Great War. The sculptor, Carles, who had been intrusted with the work, died and only last July was the monument erected in Castera-Verduzan, birthplace of the subject. The memorial is in the form of a bust on a marble column, in turn placed on a broad base, upon which is a female figure which symbolizes science. The site is the public square of the little town. Lannelongue, who was a Gascon and son of a physician, gave up a career in mathematics to study medicine in Paris, where he lived in the Quartier Latin on slender means, having as chum one Georges Clemenceau, later to be celebrated as France's grand old man. He drifted from medicine into surgery and became a pioneer in the surgery of children. His other great claim on posterity is his application of the new science of bacteriology to surgery in the days when scepticism was rife. He seemed always the first to test any new advance in medicine and had Koch's serum, the *x*-ray machine, surgical laboratory service, and similar novelties at his disposal at the earliest moment. He traveled extensively, attended numerous international congresses and combated alcoholism, race suicide, tuberculosis and other social evils in whole-souled fashion while serving as Senator.—*Le Bulletin Médical.*

RUMMO-FERRANINI GENITO-DYSTROPHIC GERODERMA (SENILISM), LEAN TYPE,

DUE TO TARDY HEREDITARY SYPHILITIS.

BY MARIANO R. CASTEX, M.D.,

AND

CARLOS P. WALDORP, M.D.,

BUENOS AIRES, ARGENTINA.

AMADEO L. M.—Spaniard, 37 years, single, day laborer, coming from Pihué, G. S. Railway, enters Ward 4 of Clinical Hospital, Buenos Aires, on February 18, 1919.

Hereditary Antecedents.—Mother died at 62 years; cause unknown; father living, family of two; one died of typhoid fever. Mother had no miscarriage.

Present Illness. The onset of his present illness cannot be well defined, and he says that his frequent colds as well as his loss of weight and comparative disinclination or incapacity for work began with convalescence from the pulmonary affection he had at 21. His general weakness has become more marked during the last two years.

Present Condition. Individual of medium stature, with bones and muscles well developed; normal adipose panicle; skin white with many achromic scars scattered about the limbs and trunk. Two of them are much larger than the rest: one, egg-shaped, about 6 centimeters in its greatest diameter, situated in the right trochanteric region, and the other, circular in form and of greater size, situated over the sacrum. Both are due to scars left by the typhoid which he had. On the left leg there is a pigmented cheloid cicatrix. There is a very plain and persistent Sergent's line.

The pilose system is poorly developed. With the exception of the scalp, where there is a fair growth, the pubic region, where it is but little, and the armpits, where it is barely outlined, the legs where there is a hair or two, the rest of the body and the face are completely bare.

Head—Large brachycephalic skull, with outer occipital protuberance highly developed and posterior fontanel depressed. Scalp healthy, light chestnut hair, scanty and dry, with slight alopecia on the temples. Forehead, with veins visible; eyebrows thin, especially at the outer end. A symmetrical countenance with high cheek bones and xerodermia, well preserved mobility and sensibility. Beardless. (See Fig. 1.)

Eyes—Normal outwardly. Mobility of the eye and eyelid normal. Slightly irregular pupils, eccentric, and apparently alike. React well to light and adjustment. Lack of conjunctival and corneal reflex.

Back of the Eye.—Papillæ with well-defined edges, without anything special.

Nose and External Ear.—Well proportioned.

Nose.—Fleshy.

Mouth.—Thick lips; teeth in a state of neglect; some badly set; microdontism in upper left incisor. The molars show the grinding surface quite smooth.

Tongue—Pink, moist, without tremor. In the upper part of the tonsil there is a slight papilloma of the size of a chick-pea, whitish in color.

Slightly ogival palate, with mobile soft palate.

Neck.—Cylindrical, long, without venous ingurgitation. Well-defined struma, soft on each side, micropolyadenopathy is manifest. Arterial throbbing.

Vertebral column.—Curved like a long-drawnout italic S; painless to pressure and percussion, with well-preserved movement.

Thorax—Asymmetrical; more arched in the left hemithorax, and more roomy (Fig. 4), with good expulsion of the breath; normal rhythm and frequency.

Lungs.—Measurement of the area of the apex, by Krönig's method, gives for the right vertex 7½ centimeters, and for the left, 8 centimeters. The base of each is on a line with the eleventh dorsal vertebra, mobile and free. Vocal resonance is exaggerated in the upper two-thirds. On percussion, sonority of both lungs rather excessive. On auscultation, vesicular murmur with prolonged expiration; some râles are present, and a good many sibilant râles throughout the lungs.

Heart.—The apex cannot be made out by inspection

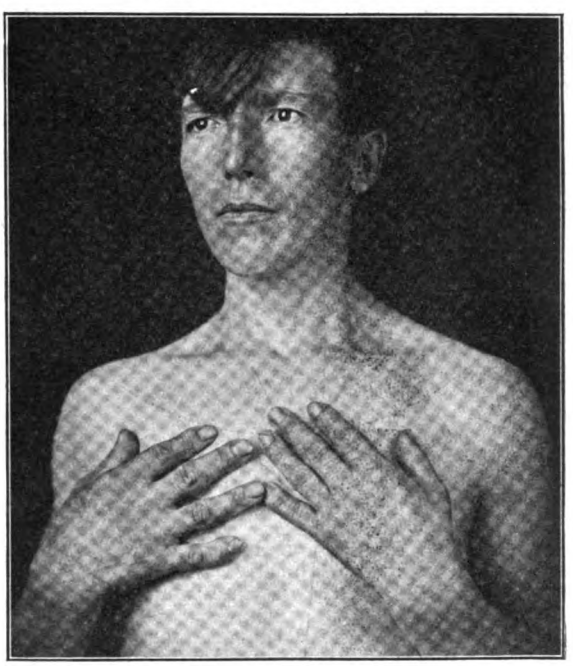

FIG. 1.—Patient Amadeo L. M.; showing the high cheek bones, thin eyebrows and large hands.

or palpation. Clear tones at tricuspid and pulmonary orifices, increased second sound at the aortic orifice. Pulse rhythmical, even, of normal tension and frequency. With Pachon: Maximum = 11; minimum = 6.

Peripheal Vessels.—Nothing in particular.

Abdomen.—Flat, with well-constituted walls; painless to palpation. The descending colon is palpable.

Liver.—The lower edge is not palpable; on percussion the upper edge is outlined in the fifth intercostal space. D. V., 14 centimeters on the mamillary line.

Spleen.—Palpable and somewhat enlarged.

Genital organs.—Penis, infantile. Testicles atrophic, painless, even to great pressure. Left testicle more atrophic than the right one. The head of the right epididymis shows slight induration. Sphincters normal.

Bony Structure.—Tibiæ, ulnæ, and claviculæ are rough.

Extremities.—Highly developed, large hands and feet. Muscular strength well preserved, tonismus, trophismus, taxis and praxis normal. Tendon reflexes well preserved, as also the cutaneous reflexes. No pathological reflexes. Standing and walking are well performed.

Blood examination (February 20, 1919).

Wassermann Test: Negative.

Red globules (per millimeter²)	4,520,000
White blood cells (per millimeter²)	10,000
Globular relativity (per millimeter²)	1 × 452
Hemoglobin	85%
Globular value	0.95%
Leucocyte Formula.	
Neutrophile polynuclear	68%
Eosinophile polynuclear	0.66%
Mononuclear	3.33%
Lymphocytes	26%
Transition forms	2%

Biopsy of one testicle. Professor Arce carried out this examination after local anesthesia with cocaine; the fragment extracted (1 cubic centimeter approximately in volume) magnified, is seen with an outer part (belonging to visceral albuminous and serous membrane) greatly enlarged, resembling lard and hard to cut; on its internal surface, it gave rise to a series of ramifications of thick connective tissue forming radiate partitions, filled with connective tissue of a later nature and small adipose balls. The wound in the testicle hardly bled.

FIG. 2.—Testicular tissue showing sclerosis, obliterated ducts and absence of interstitial cells.

Microscopical Examination.—A large amount of sclerotic tissue is observed surrounding the seminiferous ducts, grossly altered in the form of marked atrophy, intense and diffuse, and the small arteries, the walls of which appear enlarged. Interstitial cells are not to be seen. (See Fig. 2.)

Radiography of the skull (see Fig. 7).—The sella turcica is seen to be enlarged and the posterior clinoidal apophyses are turned backward.

Radiography of the Hands and Epiphysis of the Forearm (see Figs. 8 and 9). The cartilages of growth appear to be welded with slight osteoporosis in distal epiphyses of ulna and radius.

Radiography of the Pelvis.—Shows the latter to be of normal shape and size. The voice is masculine in tone.

No particulars of interest are to be deduced from the hereditary and family antecedents furnished by the patient.

In the personal record we find measles at 12 years of age, which evolved without any complications, and therefore have no importance. At 17, sickened with acute typhoid fever, keeping his bed for three months. This prolonged decubitus is of great significance in the case of *endocrinopathy*, and according to modern ideas, in accordance with endocrinological research, suprarenal insufficiency performs a very important part in the determination of the decubitus.

At the age of twenty-one the patient had an ailment characterized by temperature, cough with difficulty in expectorating which required a great effort, the sputum being blood stained. This suggests a pneumonic process to us, which, as happens in every case, takes on singular importance on account of the predisposition to tuberculosis which it fosters, and the remote action determined on the glands of internal secretion.

Some time after this he had copious epistaxes, which weakened him and has had continual colds and cough up to now, growing very thin and losing 13 kilograms in weight, with lessening of the capacity and inclination for work, all of which points to tuberculosis. Besides, he is a great smoker, which is a cause of bronchitis; this, however, may also be explained by secondary or tertiary syphilitic infection located in the bronchial tubes, so often observed, the supposition being strengthened by the coincidence of its disappearing by treatment with iodide of potassium.

Since he was thirteen he has practised masturbation, the debilitating effects of which on the psyche and nervous system in general, predisposition to diseases of the respiratory tube, heart, and digestive organs, are well known. This favors the ingrafting of tuberculosis, which, together with previous antecedents in a weak constitution and one suffering from bronchitis, lead to the idea and suspicion of a probable bacillosis, as the synthesis of the anamnesis.

To recapitulate the results of the somatic examination we find: depression of the posterior fontanel, slight alopecia on the temples, venous network on the forehead, eyebrows thinning toward the end, irregular and eccentric pupils, aniso and microdontism, ogival palate, microadenopathy, splenic tumor, cardiohypertrophy (contributing causes to which are: Hereditary syphilitic infection, smoking habit, and onanism), aortitis and rugose bones. These indicate that our patient is branded with very numerous stigmata of hereditary syphilis, some of which are original stigmata, and not of active hereditary infection, all confirming the synthesis of a dystrophic hereditary infection (syphilitic). Furthermore, we have a series of manifestations on the side of the respiratory organs: the thorax, seen on inspection to be asymmetric, with greater arching of the left hemi-thorax; chronic bronchial catarrh and emphysema, the origin of which may be attributed to the triple action at work: in this case tobacco, hereditary infection, and tuberculosis. We must not fail to remember the frequent presence of acute and chronic bronchopathies in secondary and tertiary infection, which affords an excellent soil for the bacillus of tuberculosis—the frequent existence of which is proven by the efficacy of iodide of potassium in chronic bronchitis; in the present instance, treatment by mercury and iodide sufficed to banish the bronchial phenomena.

But the most interesting group of symptoms which induces us to present the case is instanced by a condition of pluriglandular dysendocrinea.

This is how we might decompose this complex of manifestations: A slight hypothyreosis represented by soft and well-developed thyroid enlargement, thinning of the hair in the region of the temples, as well as in the tip of the eyebrows, and dental dystrophy related surely with disorders of onteo-

genesis, of hereditary syphilitic origin. A slight hypo-epinephria, marked by: pigmentary cicatrices (which can be produced by means of the caustic test), the positivity of Sergent's line, arterial hypotension, and the recorded data about easy fatigue, muscular asthenia, etc.

Another group of symptoms points to a very pronounced dyspituitarismus, namely, large face (compared with the skull), facial angle very pronounced, occipital prognathism, cervicadorsal typhosis, large hands and feet, massive, rapid, precocious growth prior to puberty, and enlargement of the sella turcica as shown by radiography. Thus grouped, these elements are typical of acromegalic hyperpituitarism. There remains still another aggregate of symptoms which we are about to analyse: Scanty growth of hair on the pubis, complete lack in the axillæ, on the trunk, face, lips, and chin, and only a few scattered hairs on the legs.

The face is singular in appearance: beardless, parchmentlike, xerodermic in a very intense degree, thick-lipped mouth, ogival palate, and teeth of the description already given.

As to the genitals, we find a small hypoplastic penis, with atrophic testicles and epididymis; the testicles painless to pressure and almost completely ederosed; to which may be added imperfect erection and problematic ejaculation.

These elements all go to show typically a state of hypogenitalism, and a clinically well-defined form of the same—Eunuchoidism.

We mention eunuchoidism for the reason that in the present case there exists a condition *sine qua non* of the same, namely, the precocious, prepuberal syndrome; were it not so, the essential condition would be lacking, *i. e.* the production thereof before the end of the crisis of puberty, characterized by the anomalous skeletal development present in the patient. Were this lacking, even with genital disturbances, there would be no question of eunuchoidism.

The cause of enunchoidism resides in hypogenesia of the sexual glands, which may be congenital, either through hypoplasia or through inflammatory fetal lesions of the same, or acquired at an early age in consequence of inflammation or traumatism. At other times, it runs in a family, or has a transitory character. In post-mortem examinations testicular lesions are revealed, extending to the seminiferous ducts, besides varied interstitial lesions.

Three principal types of eunuchoidism have been classified:

A.—Eunuchoid feminism, which is distinguished by feminism or infantilism, with a round face, feminine distribution of fat which gives to the individuals rounded outlines; hair on the pubis with feminine symmetry, lines of the skeleton of the same character; fine, delicate skin, long hands, and lower limbs very long in comparison with the body.

B.—Rummo and Ferranini's genitodystrophic xerodermia[1], a syndrome described by these authors in 1897, typified by senilism of the face and skin, with modifications of the skeleton and cutaneous disturbances which we shall proceed to detail. It has been studied and described later by Ferranini[10], Greco[11], Rummo[12], Callari[13], Bertolotti[14], Widal et Digne[15], Biedl[16], and others.

The term xeroderma was used previously by Sonques and Charat in referring to a xeromorphism presented by a girl whose skin, consequent on an eruption, took on a senile aspect; but in her case there was no genital disturbance. The denomination was altered later by Ciauri[2], a pupil of Rummo's, in favor of "senilism," which is indisputably preferable.

The appearance of the skin in these persons is characteristic; it becomes wrinkled on the face like an orange peel, to which it is aptly compared, reminding one of elderly wax or an old parchment; if we add to this the absence of a beard—facies glabra—with scarcely a downy hair, Rummo's classic expression: *sono giovani e sembrano vecchi; sono vecchi e sembrano giovani*;[3] a combination which they display from an early age, making it impossible to state their age, thus keeping "the secret of youth, the charm of which they never possessed."

The skin on the rest of the body turns rugose, loose, very elastic and of a yellowish tint; it lacks hair almost entirely in the armpits, on the chest, lower extremities, etc., and at the most a slight down covers the parts enumerated; there may be a few thin and rudimentary hairs on the pubis and where they are many, they are distributed in a feminine fashion, that is to say, demarcated above by a horizontal line.

The hair of the head is generally harsh, dry and lustreless, prematurely gray, and, more or less, thin. The eyebrows keep their vigor or thin out at the tips. The hairs in the nostrils are reduced in number. The skull, ordinarily dolichocephalous, shows a prominent occiput and the other bony protuberances are marked. The bones of the face form two exaggerated prominences: malar and mandibular.

The lower lip is thick and prominent; the teeth are poorly formed and worse set; the palate is ogival and with a projection, noted by Sterling in the center of the arch.

The sella turcica is seen radiographically to be enlarged, which indicates an alteration of the hypophysis associated with this syndrome, a point upon which not all authors are in agreement. Oscar de Souza and Aloysio de Castro[9] favor the opposite, that is to say, the sella turcica of normal size and, consequently, the physiological functioning of the hypophysis in these patients. Pende, on the other hand, maintained the increase in the sella turcica and the early hyperpituitarism, as a result of hyperplasia or adenoma of the hypophysis, a reason in accord with the achromegalism of such patients, with the rapid and precocious growth of the limbs noted in them, before puberty, and the arrested growth at the time of pubescence, contrary to what happens in the case of purely genital insufficiency. Besides, this lesion would explain the frequency of insipid diabetes, a syndrome so often associated with lesions of the region of the hypophysis.

Xerosis or xerodermia is accompanied by cervicodorsal xiphosis, the upper and lower limbs being disproportionately long in comparison with the trunk, with large and massive hands and feet (foot like a sucker and hand like a frog), the fingers being susceptible of hyperextension, and slight valgism of the ruces being coexistent.

The pelvis keeps the proportions and conformation normal in the man, or undergoes a slight widening which may give it a feminine type.

The bones become brittle, which is in contradiction with the apparent robustness of these individuals; hence the frequent occurrence of fractures in these cases.

There is a slight process of rarefaction of the epiphysis, linked possibly with an excessive loss of calcium salts, through the emunctories. The somatic development is rapid and precocious, but is arrested at the age of 17 to 20 years, the stature being medium or below normal. The subject may get stout or remain thin (lean type). The penis and testicles remain infantile; in some cases of tardiness, the testicles are of small size, or exceptionally they remain immodified; their consistency is usually modified and not infrequently a hardening is noticeable. The genesial function may be abolished absolutely—*impotencia coeundi et generandi*—with absence or erotic ideas. In other though rare cases, erections and ejaculations may occur, but insufficiently and rarely. Intelligence may continue to be normal.

Generally speaking, this is a spontaneous congenital syndrome which does not affect the health. Cases have been known of hereditary transmission.

Ciauri relates a case with severe testicular sclerotic atrophy and partial persistency of the interstitial cells. Polyuria and inspid diabetes may exist concomitantly. Falta[6] has pointed out the presence of mononucleosis in the blood formula. In a word, each and every one of the symptoms that constitute the case are to be found faithfully repeated in the present case. Hence, we diagnose xerosis, genito dystrophic xerosis, or Gerodermia Rummo and Ferranini.

Ciauri (*loc. cit.*) gives its pathogeny as follows: Three endocrine glands are out of function—the genital, causing the special morphological changes; the hypophysis, inducing gigantic scerosis through hypertrophy of the anterior lobe or hypoactivity of the posterior lobe; and the alterations attributable to the thyroid, represented by the xerodermic, cutaneous changes and those of nutrition. Therefore it is these manifestations—clinical, hypophysiary, and thyroid, which give the particular stamp which distinguishes these cases from other eunuchoid conditions.

We shall insist on this particular, recalling that there were symptoms of hyperpituitarism in our patient; but it is likewise necessary to acknowledge that the abnormal length of limb compared with the trunk, the great genital deficiency, and the lack of secondary sexual characteristics constitute the two groups of fundamental symptoms of xerosis, and are directly due to hypogenitalism, which occupies the first place in the picture of the disease. The Rummo-Ferranini syndrome is therefore a pluriglandular one, the genital gland predominating.

C. Falta's tardy eunuchoids remain to be mentioned, being those which appear after normal general and sexual development, or say the marriageable age, which show regressive symptoms. The typical want of proportion in the growth of the skeleton, found in eunuchs and eunuchoids, is not shown in these cases. They, according to Falta, would be cases of congenital meiopragia, with an added infectious or traumatic etiology (as happens with those who ride a great deal, like the tribes of "mujérados" in New Mexico, giving rise to atrophy of the testicles with retrogression of sexual characteristics—secondary ones—psychic feminism and gynecomastia. The evolution of the disease is slow, complicated and serious, so much so as to endanger the life of the sufferers, in whom supervene symptoms indicating hypothyroidism and hypoadrenia, (the latter probably a sequel to an infection such as tuberculosis, rheumatism, syphilis, mumps, etc.) which later assume the character of pluriglandular dysendoerinism.

In the present case, we think the etiopathogeny indisputable, and do not hesitate to refer the process to an infection of which the patient bears the stigma in full force—and which is hereditary syphilitic infection.

True it is that he had typhoid fever when seventeen years of age, and, therefore, we wonder if that may have been a contributing cause; but seeing the age of the patient at the time we cannot take into consideration such a possibility; besides the syndrome presented in the Rummo-Ferranini case is congenital and premature, with prepuberal, rapid development.

We wish to emphasize the fact that syphilitic and hereditary-syphilitic infections are a very frequent cause of endocrinopathy, provoked, in most cases, by an attack of any kind of infectious disease, and thereafter the mobilization of latent infectosyphilitic processes which affect the organs variously.

There is only one case in literature with hereditary syphilitic antecedents, namely, one published by Fragola[8], the child of parents who were both syphilitic, the falsetto voice, lack of spermatic secretion, child mentality, etc., being present together with genitodystrophic xerosis. The author attributes it to a pluriglandular endocrinopathy, with deficiency of testicle, hypophysis, thyroid and suprarenal glands.

The syndrome is very unusual in women. Paolo Bueri[7] reports the case of a girl who, at fourteen, had the face of an elderly person, did not menstruate; she had a large clitoris and infantile uterus, and was without any pilose growth in the pubic region. The voice was nasal, almost masculine in tone. The right lobe was not felt in the thyroid, while the left one and the isthmus were palpable.

Our prognosis of the bronchial process was optimistic, and in effect it was cured. On the other hand, in view of the mature years of the patient—37—our prognosis of the syndrome—genitodystrophic xerosis—was very pessimistic indeed.

If, in these cases, the diagnosis could be made at an early stage and a treatment prescribed equally early, the prognosis would be favorable, and we should prevent their reaching the stage of irreducible sclerosis of the testicle as in the present case.

We gave the patient 40 injections of 0.02 centigrams each, alternately, of bicyanide and biiodide of mercury; and besides, we administered through the stomach, iodide of potassium in doses of from 2 to 4 grammes daily for eight months, without any retrocession of the testicular sclerosis.

Furthermore, opotherapy was prescribed with Denys-Dessy's extractum testis. Still persists absolute impotency. It was expected that a testicular graft might be carried out, but the opportunity did not offer. Complementary pluriglandular opotherapy is now being tried.

We believe that the claims advanced by Rummo at the Congress of Rome in 1914 was justified, demanding that the paternity of the syndrome be ascribed to him, and besides, that the classification should not be withdrawn as was suggested by some. (Chauvet[9].)

THE QUESTION OF THYMIC EPILEPSY;

WITH REPORT OF A DEMONSTRATIVE CASE.

By WILLIAM BROWNING, M.D.,

BROOKLYN, N. Y.

Is there such a thing as thymic epilepsy? The suggestion of such a form has been made on theoretical grounds, somewhat analogous to the blank spaces in tables of the chemical elements. As yet, however, little appears to have been accomplished either in establishing the existence of this form or in developing a clinical picture for its recognition. The main attempt in this direction will be cited at the end of this paper. It is consequently important to make a definite start; and single cases are of signal value for this purpose. It is now possible to recognize the thymic element in these cases—by means of the *x*-ray in some, of careful percussion in most, and of a history or evidence of thymic effects in all —far better than in the past.

A word may be said as to what is meant by thymic epilepsy. Of course in practice most cases of epilepsy represent a combination of factors. But now and then at least we ought to encounter relatively pure forms, if lymphothymatism ever plays a rôle. In those of pure type there are certain demonstrative elements, such as (1) the presence of thymism; (2) the absence of other recognizable cause, as heredity, degeneracy, morbidities not of thymic origin, etc.; (3) peculiarities in the course of the epilepsy itself. For clinical purposes we can consider such a diagnostic triad as sufficient. When, in addition, cases of the kind multiply, the proof becomes positive.

It may be well to recall the fact that a number of sub-forms of epilepsy have been differentiated, as summarized by Dercum and others. These include the primary or idiopathic, Jacksonian, the secondary group (as the post-hemiplegic of Dunham)[1], nocturnal, possibly a reflex, senile, traumatic, toxic, cardiac, uncinate, luetic, larvated, endocrine, etc., these at times overlapping. It is as a member of the last, or endocrine group, that the thymic form finds its place of interest.

The patient was a man of 25 years when seen April 28, 1920, with Dr. George Manulkin of Brooklyn, who has kindly given important particulars. He was born in Russia, coming to America 8 years ago. Is unmarried, and the first of 7 living children, one older having died at two years of age. Parents alive and without blemish. He began to walk before he was a year old. Bronchopneumonia at one year of age and "very often" for some time after. Such attacks (bronchitis and bronchopneumonia in the young) are so commonly associated with endocrine abnormalities at this period, whether as cause or effect, as to indicate the early origin of his condition.

He had "spasms" when a baby of two years, and a second time two years later—quite the rule in thymic rickets. The patient says that nocturnal eneuresis persisted, "I think once a week," until 9 years old. This also has a bearing, as late continuance of this habit is specially common in subjects of thymism.[2] The patient says he had three kinds of typhus (typhoid?) at 16 years of age in Russia. And while still there a doctor gave local treatment for relief of nasal block. This last condition also fits in with the picture of lymphatism.

He attended night school after coming here, and speaks English well. Is a clothing cutter by occupation. Appetite regularly good. Maximum weight 145 lbs. Bowels regular. But little fermentation (gas). No dizziness, tinnitus, headache, nor much sweating. Sleeps soundly 9 hours. Is restless, snores, and sometimes talks in sleep, but knows of no dreams.

Sighing and deep respiration often. Has times of dyspnea. "I can't run," but "I can walk fast" and far. Sometimes for a whole week his breathing shows "six beats weak" and then one strong. Has palpitation after climbing stairs. These things also, in a young man of good physique and not a nicotinist or other habitué, are suggestive.

The first seizure of his present trouble was at a theater in the fall of 1916. On coming to, he found himself on a fire-exit balcony, and thought it had been only a faint. He was then free until October, 1919, when sitting and talking in the early evening he "fainted" and fell from the chair. A recurrence took place on April 14, 1920, about 6 P. M., when he fell while standing and talking on the street. Of minor seizures nothing is known. He is convulsed and unconscious in all attacks, each in the early evening. The convulsions, as described by others, are general and severe. The doctor states that there are punctate subcutaneous hemorrhages in the face after a seizure. There was also some nasal hemorrhage in the last two attacks, and even a little bleeding from the mouth once or twice. He does "not feel good in the stomach" when he gets the seizures. Has trouble in getting his breath, and "heart beats fast" after one.

The patient is a vigorous healthy-looking man with no suggestion of mental impairment. Weight 142 lbs. Height 65 inches. Pulse 72. Systolic pressure 127 mm. Cardiac sounds all clear. Pupils equal, normal, react well to light and accommodation. Cephalic index 84.

FIG. 1

Percussion shows high dense dullness in the thymic area (Fig. 1); this extends a little farher up on the left than on the right, as is the rule in thymomegaly. Somewhat depressed lower sternum, but prominent manubrium. The skin capillaries, in this region at least and on the hands, show great reaction to pressure, practically tache cérébrale. This reaction can still be evoked (September 9); and as it occurs in similar cases it may be due to the general condition of status lymphaticus.

No marked tremor of hands. Nails short and flat. Teeth short, well kept. Tonsils small. Tongue slightly coated. Many large cervical glands. Nostrils not blocked. Mouth not gaping.

Various slight marks of early rachitis—clubbing at wrists, knees 3.5 cm. apart, sternum, faint cross-marking of lower incisors, etc.

For the *x*-ray picture of the thymus, Fig. 2, taken at this time, the writer is specially indebted to Dr. John G. Williams. The patient then had a series of five *x*-ray treatments, first a set of three and a month later two more.

Seen again August 7. No seizure of any kind since. The thymic dullness on percussion has entirely subsided. Pulse 70, varying oft a trifle in rhythm. Looks plump, ruddy, and bright. Cervical glands are all notably smaller, but still palpable (shrunk to normal a month later).

That this was a case of thymism is proven by the history, the presence of a persistent thymus, and by other clinical findings. That it was also a case of epilepsy is sufficiently clear. There might still be a question whether it was thymic epilepsy, or only epilepsy in a thymic subject.

The effect of treatment is not always decisive here. It takes too long to be sure of the outcome; we cannot control all thymic sequels with certainty; the habit element in convulsions cannot be discounted, and mere novelty of treatment may act for a time. So far, however, the result in the above case is satisfactory (no recurrence now in nearly seven months).

The type of epilepsy in this case is somewhat distinctive. The character of each seizure right from its onset rules out Jacksonian and most secondary forms. The age, appearance, and history of the patient exclude various other forms. No trace of mental defect or loss, ruling out primary degenerative types. The onset at 21 was later than is general in the idiopathic, though this form is only recognizable by the absence of other assignable cause. Venereal denied; and no evidence of lues.

The fact that the seizures were only at long intervals distinguishes this widely from thyroid, or better hypothyroid epilepsy. The latter occurs in the earlier years of childhood, shows frequent seizures, lasts for considerable but yet limited periods, and then is usually cured or may subside.[3] Though the clinical type therefore may not be absolutely exclusive in this case it is sufficiently so to be available in differentiation.

And in this case no other cause was found. Hence the triad of reasons, above formulated as warranting the diagnosis, can be fairly considered as met, so far as one case goes. The writer has occasionally seen cases of like character, and therefore with the greater confidence puts forth the above case as representative of a type that deserves general recognition. The ear-marks of thymism (thymolymphatism) are often sufficient to warrant a presumptive diagnosis, even without the confirmatory *x-ray*.

Whether the epilepsy in such a case is a direct result of the thymolymphatism, or is due to secondary conditions, is not material to the general question of its thymic origin. The epilepsy can be conveniently figured as a net result of direct and correlated thymic influences.

There are three lines, it has been thought, along which such influences may act. One of these can be termed the biochemic (short for biological-chemical). The "lymphotoxemia" of Warthin, "thymotoxic serum" (Ogata), and "sensitization of the tissues" with resulting convulsions as "anaphylactic phenomena" (Symmers 1917) can be regarded

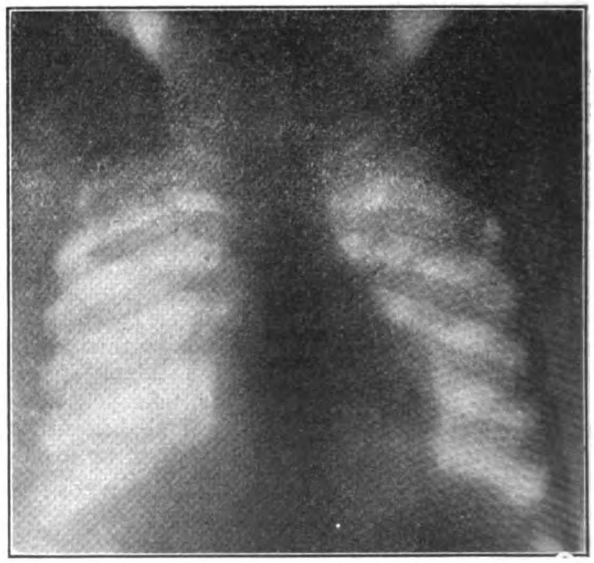

FIG. 2

as suggestions of this order. The second is the mechanistic view. In this sense the circulatory and especially respiratory peculiarities of this case, in harmony with known effects of thymism, indicate one way in which the morbific influence is exerted.

A third way is by reflex action. That various neuroses and other pathological conditions are at times a result of thymism is not strange, as the same holds true for such causes as syphilis, tuberculosis, and alcoholism.

The management of this type of epilepsy offers problems of special interest and promise. Reduction or removal of the persistent gland (*x*-ray, radium, thymectomy), though of primary importance, is not all. Activities that tend to expand the upper chest are advisable. The circulation may need some care. A slight stimulus to the thyroid function is required in some. These sufferers ought not to follow an office, subway, or factory life or other occupation where bad air is unavoidable. Other special indications are to be noted in individual cases.

Where all these indications can be met and early treatment instituted, there is prospect of better results that in most forms of epilepsy with which we are familiar. While the proportion of epileptics in whom the thymic element is the chief cause may not be large, the total number of such cases must be considerable. Both theoretical and practical interests call for a better understanding of this type.

Little help, however, is to be gained by attempting to collate the literature of the subject, for the most part mere opinions. But this report cannot be closed without mention of the well-known work of Dr. J. P. Ohlmacher. This was published in several papers.[4] He described four or possibly five cases, including the autopsy findings, all of long standing. His sweeping views have not been everywhere corroborated. He has a basis of fact, though not of a kind to be accepted fully as proof. Palmer of Australia (1914), the late Dr. Karpas of New York, and others have made confirmatory observations.

Before Ohlmacher's material can be advisedly discussed now, we need a standard type or types as criterion. Clinically his cases differed from the one detailed in this paper. The nucleus of fact can best be established by the accumulation of selected cases that have not reached the degenerative state frequent in the institutional class.

As there may be other types of epilepsy in which lymphatism is a factor, it may be well to preempt for this form the designation "Thymic Epilepsy, Type A."

54 LEFFERTS PLACE.

Chorea of Syphilitic Origin.—Cassoute and Giraud report three cases of chorea in children in which there was a lymphocytosis of the spinal fluid and positive Wassermann. The patients were rapidly cured by neosalvarsan, although in two of the cases the chorea appeared to be chronic. In one case the Wassermann became negative with surprising quickness.—*La Presse Médicale.*

DIATHERMY AN AID IN EMPYEMA.*

BY A. B. HIRSH, M.D.,

NEW YORK.

PROBABLY never before had practitioners met so many cases of hemolytic streptococcus empyema as occurred in certain army camps in the winter of 1917-1918, of empyema that followed the various chest wounds of the World War and, more especially, its accompanying pandemic of influenza.

Many of these cases began as a *Streptococcus hæmolyticus* pleuritis, a very different condition from the pleural sac inflammation usually seen in practice.

The former, as a rule, never had any previous infection, either of pneumonia or influenza or trauma; it *began* as an empyema. The empyema that was a *Streptococcus hæmolyticus* infection of the pleural cavity presented all the difficulties of treatment that this organism usually shows, plus the problem of combating any intrathoracic disease. Its mortality equalled or even surpassed that seen in influenza, but the cases were limited to army camps and were not noted generally in the civilian population.

It naturally follows that such an exceptional clinical opportunity should have led to research work the results of which give promise of much better technic in treatment of this previously intractable disease or sequel. One need but briefly refer to betterment of the Estlander rib resection, to the use of Dakin-Carrel irrigation, to Carl Eggers' routine decortication for restored lung expansion, to cite the main stages of the modernized operative procedure.

Cases of empyema uncomplicated by osteomyelitis are as a rule successfully treated by complete decortication. Unfortunately this complication is rather common, due not alone to the fact that a rib resection has been performed, but, in particular, because the rib was infected along with the primary process. Captain William S. Long† has records of a number of such patients, one being the case about to be described. There occur, however, certain instances of empyema where even most persevering, faithful attention to approved surgical technic fails to induce closure of the diseased chest cavity, where the infective process refuses to yield although repeated change is made in chemical agents intended to check the purulent secretion. Such disappointing results are not infrequent experiences with surgeons having large clinical facilities everywhere. It was under such circumstances, beginning in December last, that a number of cases at Hoff General Hospital were referred by the Surgical Section to the Section on Physiotherapy for possible betterment through application of one or more of its physical treatment measures.

The conditions faced in such a case were those dependent on an active infective process with abundant purulent output. These occurred within what was practically a closed cavity, the walls of which, through respiration, were in continual action. Two therapeutic indications were therefore presented, the first being to induce intense phagocytosis for removal

*Read at Atlantic City, Sept. 16, 1920, at the thirtieth Annual Meeting of the American Electrotherapeutic Association.

†Personal communication.

of infective material, and the other markedly to increase the arterial blood supply locally for improved nutrition of involved structures, having in mind early closure of the pleural space by enforced growth of granulation tissue.

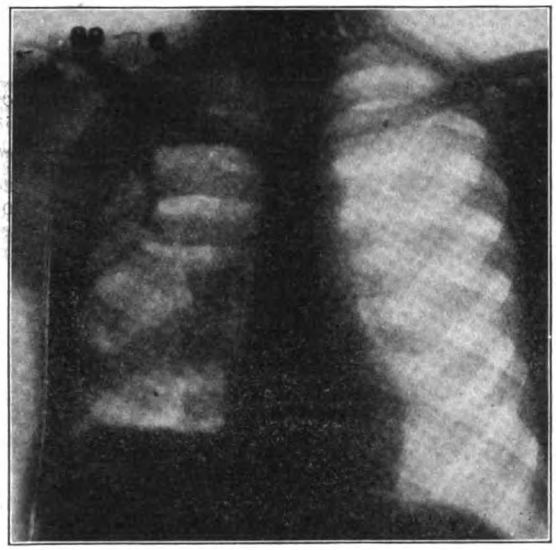

FIG. 1.—C. C. M., Nov. 2, 1919—Just before diathermy treatment began.

Until December, 1919, none of the physical measures proposed had proved successful to bring about such necessary changes—radiant light and heat, the most promising agent, being apparently too slow in action or else penetrating the chest walls insufficiently. Some more exact modality, influencing circulation directly through the chest organs, was especially demanded; so, based on its recognized mechanical action, attention was directed to diathermy, the peculiar current derived from a high frequency apparatus constructed just for this purpose.

It would be timely, in this connection, to recall the convincing experiments on egg albumen and raw beef first performed by Nagelschmidt[1] to show that diathermy acts from within and not otherwise. When fresh egg albumen is dropped on a transparent glass dish and this current passed through, a metal electrode being placed at either end, coagulation is seen to start outward from where the lines of current meet and cross; these lines are direct and not curved or irregular. The broad surfaces of the electrodes must be facing and opposite each other as, otherwise, the diathermic action is more superficial, moving mostly between the nearest edges of the metal plates instead of their largest areas. Another pertinent fact shown was that the site of most intense action could be directly controlled by the *sizes* of the electrodes, the lines of greatest heat crossing nearer the smaller electrode. The latter result could be all the better demonstrated on raw beef, whether the current is sent with or against the grain of meat. The important clinical bearing of this exact localization is readily apparent.

It was based on these facts that the use of diathermy for empyema was originated at Hoff General Hospital by Captain C. M. Sampson, chief of the Physiotherapy Service, the writer being associated with him at this time. It was the original intention to describe with some detail a series of the cases treated in this way, so as to show results on the different complications delaying a cure. The first patient so treated, however, presented such a variety of these difficulties obstructing repair that it was decided that a full account of how each of these was overcome in this case would practically cover all phases of the subject and so fully answer the object of this study.

Corporal C. C. M., white, 27 years old when enlisting, an automobile mechanic, parents living and well, no other children, had scarlatina when a child; no history of chronic disease. When taken with acute pleurisy in France, March 15, 1918, he was at once brought to a French hospital. On April 1 an operation was done on the upper posterior right chest, a tube being inserted for drainage after closure of the wound; the latter had firmly united by April 30. The wound having reopened August 18 and there being free purulent discharge, an eight-inch rib resection with decapsulation was done the following day; beside the usual incision a low-down counter-incision became necessary; the tubes were removed August 30, drainage continuing. By December 6, because of osteomyelitis of the eighth rib, a radical resection and decortification was done. This was repeated in January, 1919, but a thick purulent flow continued.

Physical examination on September 3 showed his normal weight of 130 pounds to be down to 123 pounds, although the general condition remained good; extensive scarring on the back was noted along with slightly enlarged glands in both axillæ; pulse, 140 and regular; heart slightly enlarged downward, quite rapid but with no adventitious sounds. Uranalysis at this and all other times, always negative. Blood test showed erythrocytes, 4,300,000; leucocytes, 28,000; hemoglobin, 80 per cent.; differential count, small mononuclears, 16 per cent.; large mononuclears, 15 per cent.; transitionals, 1 per cent.; polymorphonuclears, 68 per cent., of which eosinophiles were 2 per cent., neutrophiles, 65 per cent., and basophiles, 1 per cent. On September 6 roentgenograms showed section (osteoplastic flap attempted) of the 4th, 5th, 6th, 7th, 8th, and 9th ribs at the right costodiaphragmatic angle. The mid-half of the right chest is a large area of increased density probably due to thickened pleura. Again, on November 2, as seen in the illustration, the *x*-ray findings in addition showed evidence of infection of the sectioned

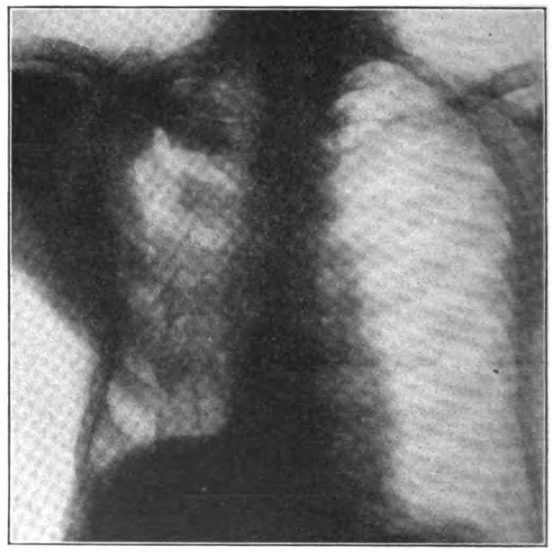

FIG. 2.—C. C. M., June, 1920. Note favorable change in symptoms.

ribs close to the angles. The right chest was flattened in the anteroposterior diameter. Three days later the 3d, 4th, 5th, 6th, and 7th ribs were resected. The pathology report mentioned a long scar extending from the 3d to the 9th rib posteriorly on the right side, the course of which was marked by five sinuses in which

necrotic bone could be probed. The incision included the scar and the sinuses. The ribs were sectioned about two inches from the angle made at a previous operation, and a portion of the fifth rib resected. Lung expanded freely, but ribs were necrotic and the anterior portions overlapped the posterior fragments; there were also bridges between the anterior portions. Rib ends were necrotic. All scar and necrotic material was removed and the entire wound closed. It became possible by December 28 for the first time to apply diathermy. It was given daily to the involved region. The one electrode, of Crookes' metal, 22 gauge, shaped like an elongated "O," was placed directly over the inflamed region, including the incision scars and the discharging aperture. The other, much larger, electrode was held over the anterolateral surface of the left chest. The electrodes were to be shifted downward in the course of treatment so as to take in areas treated by the Dakin tubes. Starting at 300 m. a. for 40 minutes, the current was in a few days increased to 650 m. a. for 60 minutes. It became possible finally to use 2,000 m. a. in such cases. When using small electrodes, it might be stated here, it is a safe rule never to pass above 700 m. a. unless actual tissue destruction is intended, an end never desired in medical cases.

By January 30, 1920, the course of the case had progressed so favorably as to encourage the addition of the ultraviolet ray treatment for systemic effect. This had in view the excellent results obtained in treating chest cases, especially tuberculosis, with outdoor sun therapy. Captain Long, in referring the cases of empyema, believed it should be equally beneficial in them, also. Each day the quartz lamp was applied, at a distance of 24 inches for three minutes, to each body region, the chest, arms and legs, front and back, being rayed in succession. Areas where diathermy was applied were avoided so as not to interfere with its continuing action. By acting on surface capillaries the blood stream would be directly influenced and an undoubted "tonic" effect obtained. Patients who had this general ultraviolet treatment showed subjectively and objectively a better morale. The appetite increased and a casual observer would never imagine that they were suffering from a serious infection limiting, sometimes by one-half, their lung capacity. The use of Dakin's solution showed this benefit, also, but patients remarked voluntarily that they "felt better" following ultraviolet therapy.

By March 29 the three upper of the five original discharging apertures, on each side of the main vertical line of incision, had closed; the main opening also became much smaller. The discharge had changed from a thick purulent to a thin serous consistence. Increased development of the soft structures of the chest, shoulder, and arm on the affected side was noted so that motion and strength in general showed a distinct gain. Reference to the second illustration, a roentgenogram taken in June, 1920, shows disappearance of osteomyelitis, and of the shadow from lymph deposit on either the pulmonary or costal pleura, while the entire post-operative cavity has finally been obliterated. Almost complete correction of the chest deformity is also apparent. Further progress was uneventful, so that by July the entire wound had closed, only slight moisture on the dressing at the former site of the lower aperture being occasionally found; all evidence of rib involvement was gone; chest expansion was free so that the right-sided concavity had disappeared; respiration, so far as physical exploration proved, was normal in both lungs. The patient's general condition correspondingly improved so that he could ultimately be discharged from the hospital and army service.

Here had indeed been a most unpromising condition: the patient debilitated from repeated major operations, long continued suppuration, and a lowered morale from prolonged hospitalization. Osteomyelitis existed in both fragments of each of the sectioned ribs, in the posterior ends almost to the vertebral articulations; until this complication ceased, the reinfection of the pleural space must be continuous. Every other surgical and non-surgical procedure had been exhausted when, finally, diathermy was employed. Such, however, was the encouragement given the surgeons that a series of chronic cases of empyema, with various complications, was sent to the Physiotherapy Section for application of the new method, and with uniformly satisfactory results. Diathermy is, therefore, now a recognized addition to the treatment of empyema at this institution.

In a study of the literature there is found a growing tendency to use diathermy, among other electrical modalities, in affections of the chest. Nagelschmidt[2] states that "in a case of acute pleurisy under my care an application of diathermy was followed by immediate relief of the acute pain due to breathing and coughing, and the pleurisy disappeared in a few days. Chronic dry pleurisy also improves rapidly under influence of diathermy and is finally absorbed." Kowarschick[3] claims that "Diathermy is generally indicated in the treatment of pleurisy, both of the serous and fibrinous varieties. Guided by the subjective symptoms, its thermo-penetration appears to cause a more rapid absorption of the exudate; the localized pains as well as the tendency to cough are much improved." Saberton[4] says: "I have had experience in one or two cases of tuberculosis of the lungs in which diathermic applications have appeared to hasten absorption of the fluid. This is a result that our knowledge of the action of diathermy would lead us to expect."

None of these leaders in physiotherapy, however, suggest the use of diathermy in the serious class of cases above referred to. The extent to which this method has been employed is as yet too limited to formulate definite conclusions; the success unmistakably achieved, however, warrants a further study of the use, on a wide scale, of diathermy in empyema, especially if of hæmolytic streptococcus origin, with or without osteomyelitis.

The writer wishes here to acknowledge the co-operation and suggestions given in the preparation of this paper by Captain William S. Long, Chief of the Operation Room, Hoff General Hospital, and to express his deep appreciation of this assistance.

71 WEST NINETY-FOURTH STREET.

A CASE OF LEONTIASIS OSSEA.

BY JOSEPH EASTMAN SHEEHAN, M.D.,

NEW YORK.

INSTRUCTOR IN DISEASE OF THE NOSE AND THROAT NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SURGEON SPECIALIST TO THE MORRISTOWN AND ORANGE, N. J., AND PORT JERVIS, N. Y., HOSPITALS.

I REPORT this case because it is one of an uncommon disease. Virchow has termed the condition "Leontiasis Ossea" (Lion's face); Ziegler prefers to call it "Partial Gigantism"; Starr calls it "Megalocephaly." It is a disease which affects the bones of the skull as well as the face. Its etiology

is quite obscure. Williams autopsied one case of "Leontiasis Ossea" and found the intracranial cavity almost normal and the brain and pituitary body were normal; parts of the skull were nearly 3 in. thick. Schwartz considered its cause possibly due

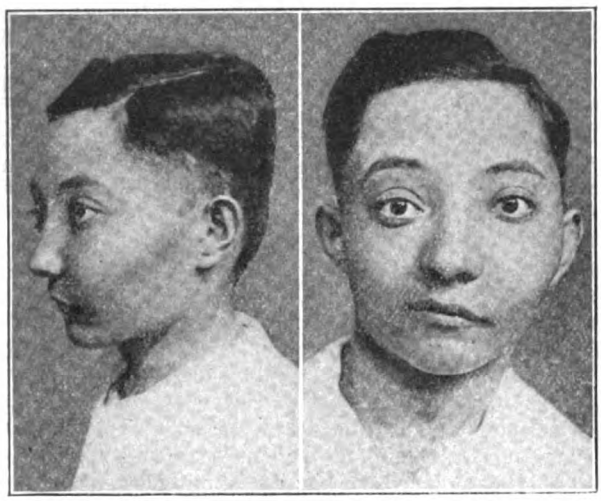

FIG. 1.—Leontiasis ossea.

to nerve lesions near the base of the brain and that syphilis might be a factor in its causation. The disease begins in youth in otherwise apparently healthy persons and lasts many years.

The enlargement of the bones must be either (*a*) simple hypertrophy, (*b*) new growth, or (*c*) chronic osteitis. The appearance negatives the first two and accepting the last view, there is some difference in opinion as to the cause.

The majority of cases recorded had a history of an injury, and in my case, the malady seems to be quite clearly connected with an injury. Bland Sutton thinks that rickets is the fundamental cause; the scoliosis and pelvis might be regarded as static

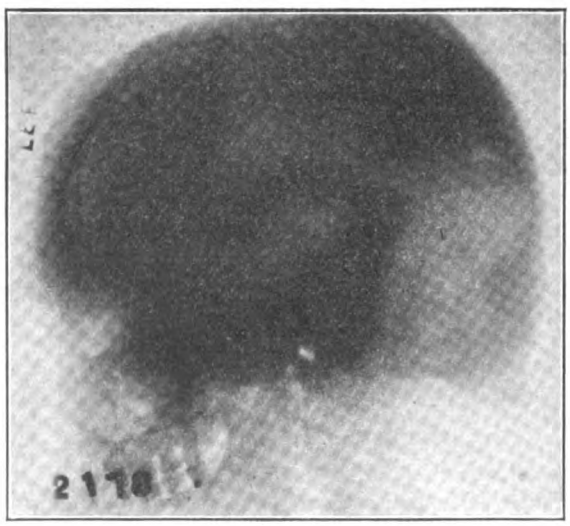

FIG. 2.—Lateral view of the skull and face. Note the obliteration of the ethmoidal labyrinth.

in origin and due to the weight of the head. Against the theory of rickets there is no tendency in the pelvis or in any of the long bones of the lower limbs towards buttress formation, which is so common in rickets (Stark).

The possibility of the osteitis being syphilitic must be considered and is impossible to negative. Paget's disease, which the thickening of the skull at first suggested, does not occur in children, does not affect the bones of the face, and generally is well marked in some of the long bones. It chiefly belongs to the senile periods of life; it may occur in either sex, but is more frequent in men; it often happens to those of a gouty family history.

Acromegaly affects the bones of the feet as well as the face bones and not so much the cranium. In acromegaly the lips and tongue and other soft parts are thickened. There is nothing suggestive of cretinism or achondroplasia.

The records of the cases autopsied showed a uniform thickening of the skull and all the bones of the face. On section, bones of the skull were much softer than normal. There were areas of much compact tissue and in other parts great areas of rarefaction. The skiagraphs in my case also show areas of condensation throughout the entire vault with areas of rarefaction, and areas of osteoporosity as noted throughout the skull. The pituitary is normal. The least affected portion of the skull is the occipital bone. The thyroid in some cases showed organic changes. The pituitary in all cases was normal.

History.—Herman W., aged 24, born in 1896, admitted to the Post-Graduate Hospital for nasal hemorrhage and difficulty with nasal breathing. Father and mother are dead. Father died from malarial fever at 40; mother died of rheumatism of the heart at 32; one sister died in infancy. Father and mother were not blood relations. Mother has had two children, this being the eldest. She has had no miscarriages; labor tedious in both, otherwise normal. No evidence of syphillis in parents or other children. No other member of the family of either side similarly affected. No tuberculosis or insanity.

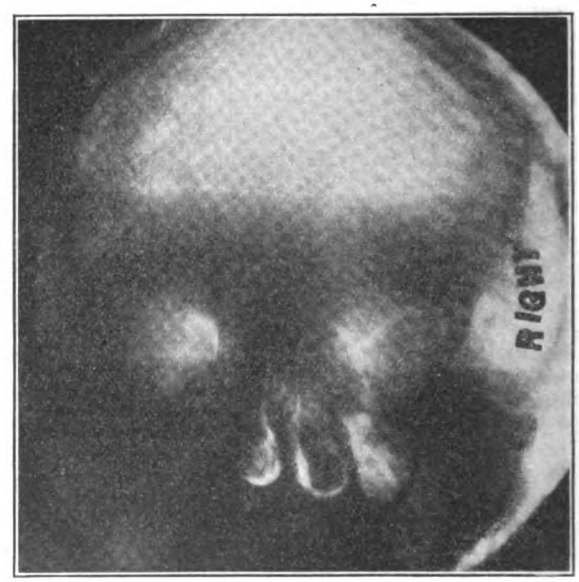

FIG. 3.—Skiagraph showing anteroposterior view. Note the clear airway on the left side of the nose after radical septum operation and chiselling away part of the floor of the nose.

As a baby there was nothing abnormal noticed; when at the age of five years, as a result of his father having died and his mother being in poor health, he was placed in an orphan asylum. During a stay of six months at the institution he was on several occasions beaten over the head with a club, the last time severely,

which caused considerable swelling on the left forehead and face. About the seventh year, hats worn by children of 10 or 12 years of age were the only ones which fitted him. As a child he was mentally as other children, and has never been in this respect deficient. At the ages of 6, 9, and 13 years he had diphtheria, and only in the last attack was he treated with antitoxin.

At the age of eight years the swelling of the left side of the head and face become so noticeable, he was examined by several physicians.

In 1912 he was again examined, as the swelling of the head and face was progressing with great strides. A diagnosis was now made of multiple osteoma. At this time a swelling of the right upper lateral spine was noticed (lateral curvature), with a prominence of the left ilium. He has never suffered from pain or headache, and has been dizzy only on one occasion, some seven years ago. Hearing in the left ear is somewhat impaired. Wassermann negative.

In 1919 a fracture of the right femur caused him to be confined for three months. The right leg is shorter than the left. The recorded measurements of the head and jaw are: (1) Bitemporal, 36.5 cm. (2) From most prominent part of occipital bone to the glabella, 41.2 cm. (3) Circumference, 66.5 cm. (4) Right angle of jaw to chin symphysis, 11.8 cm. (5) Left angle of jaw to chin symphysis, 13.5 cm. The left side of the face shows a huge osseous hypertrophy involving the frontal bone and the upper and lower jaws. There is an enormous enlargement of the left upper alveolar process. This gives the patient an asymmetrical, distorted appearance. (See Fig. 1.)

The measurements of the thickness of the skull as taken from the skiagraphs are: (*a*) Frontal bone at the site of the frontal eminence, 4 cm. (*b*) Through the roof of the orbit, 2.5 cm. (*c*) Vault varies in thickness from 2 to 2¼ cm. (*d*) Occipital protuberance, 4.5 cm. (*e*) Occipital bone at the junction of the parietal bone, 8 mm. (*f*) The pituitary measures 8 mm. by 8 mm.

The anteroposterior view of the skiagraph (Fig. 2) shows a complete obliteration of the frontal ethmoid and left maxillary sinus, by dense opaque bone with an encroachment upon the orbit of the bony structure making up the same. The right maxillary sinus is clear.

On April 10, 1920, a radical septum operation was performed by me, in which part of the floor of the nose was removed, for the purpose of giving him a better airway. The result is shown in Fig. 3. This patient has been treated on syphilitic lines without any results.

24 East Forty-eighth Street.

DERMOID CYST OF THE MEDIASTINUM WITH TRANSMITTED PULSATION*.

By H. E. HALE, M.D.,

NEW YORK.

In the *American Journal of the Medical Sciences* for August, 1916, Hertzle[1] reports a case of mediastinal dermoid and reviews with bibliography, seventy-two found in literature. For some reason he omitted a case reported by R. Belin.[2] Belin twice operated on his patient. His incisions were in the right anterior chest below and outside of the nipple. The patient made a complete recovery after the second operation. Since the time covered by Hertzle's report, I have been able to find only two cases reported. These were reported by Körner.[3]

The years of early adult life are the ones when dermoid cysts and teratomata are most likely to make themselves known. They are about equally as common in men as in women.

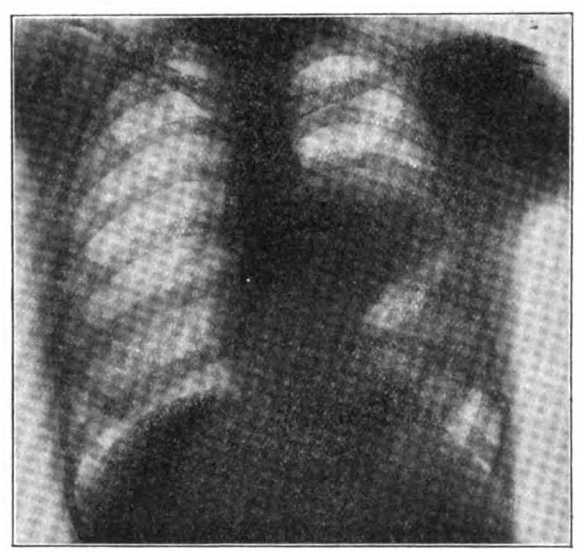
The usual symptoms are due to pressure or irritation, especially of nerves. There may be a cough. Dysphagia is uncommon. Clubbing of the fingers is very rare and when present may be the result of a coexisting pulmonary tuberculosis.

Not only the proximity of essential structures, but the actual attachment to them most often determines what surgery can do in each instance. With this in mind it is of interest to note that Hertzle in the cases he has analyzed finds that 7 were connected with bronchus; 12 were adherent to the pericardium or pleura; 9 were attached to or protruded into the lung; 11 were attached to the diaphragm; 4 were attached to the large vesels; 1 was attached to the chest wall; 11 extended into the lobe of a lung.

Case of Daisy C.,* age 21, admitted June, 1919.—The possibly relevant points in the previous history are: uncomplicated influenza 8 months ago; pleurisy 8 weeks ago; cough for 3 weeks, twice with blood-streaked sputum.

The patient is well nourished, but is distressed, and complains of great left thoracic pain. Severe pain was her chief complaint.

In the left 2d, 3d, and 4th interspaces, extending from the margin of the sternum to the mid-clavicular



line, there is distinct pulsation seen and felt. It is synchronous with the heart beat. There was neither thrill nor murmur present. There was dullness, not flatness, and distant bronchial breathing with muffled spoken voice over the pulsating area and also just below the posterior pulmonary apex. There were a few moist râles heard at the left base, front and back.

Fluoroscopy "revealed a pulsating mass, apparently entirely independent of the heart shadow. Its base was at the hilus of the lung." The left dome of the diaphragm was markedly raised by "adhesions" which blended with the pericardial shadow. There is pulsation of the diaphragm synchronous with the heart beat apparently caused by the "adhesions." The original diagnosis was encapsulated pulsating empyema with its origin apparently from the hilus of the lung or the mediastinum. The radiologist reports simply, "wedge-shaped area of diminished illumination of upper and middle lobes of the left pulmonary field." Diagnosis: Interlobar abscess.

The patient was in our ward for a number of weeks. I examined her frequently, studied the picture on the fluoroscopic screen and the radiograph, as well as twice aspirating her of a thin bloody sterile fluid.

My interpretation of the condition differs from the one given with regard to the left base. The very unusual outline and the pulsation of the diaphragm I believe to be due to post-pericardial extension of the upper mass

*From the Tuberculosis Wards in Bellevue Hospital.

downward to the diaphragm and thence between the lung and the diaphragm toward the costophrenic sinus. The wall of the interlobar portion is very thick and tough. It required much effort to push a needle through it 8 c.m. before its cavity was entered.

There was considerable pressure exerted on the heart, as is shown by the bulging into the right hemithorax of the upper part of the heart shadow, as well as by the pulsation of the mass, which must, by necessity, be a transmitted pulsation.

Aspirations always gave relief, if a fair amount of fluid was removed. Seventy c.c. was the most I ever drew off at one time. The patient's greatest relief came when the sack drained through the trachea. This occurred several times in small amounts and once in considerable quantity, after which pulsation ceased and she greatly improved and left the hospital. The surgeons consulted did not advise an operation. No tubercle bacilli were ever found.

The subsequent history is as follows:

About the first of November, 1919, she went into Mt. Sinai Hospital. At this time there was no pulsation of the mass. Dr. Lilienthal opened the chest by lateral thoracotomy. He found the mass to be a dermoid cyst. It was too adherent to vital structures to permit of removal, so he evacuated it and sutured it to the chest wall. The patient made a god recovery. She was out of bed on the fifth or sixth day.

I last saw her about the middle of March, 1920. She looked well and said she felt well. Her only inconvenience was a sinus which discharged a small amount of serous fluid.

A CASE OF CHRONIC (RESIDUAL) ENCEPHALITIS LETHARGICA, SIMULATING THE PARALYSIS AGITANS TYPE, IN A BOY OF 16 YEARS.*

By JOSHUA H. LEINER, M.D.,

NEW YORK.

ADJUNCT ATTENDING NEUROLOGIST LEBANON HOSPITAL; CHIEF OF NEUROLOGICAL CLINIC LEBANON HOSPITAL.

Patient J. B. is sixteen years old and born in Russia. Family and previous history entirely negative. He was a bright and cheerful lad, interested in affairs corresponding to his age, was never "left back" in school, and behaved well at home. In December, 1919, he was sick in bed for five weeks with what his family physician said was pneumonia. Close questioning points, however, to an influenza-like infection. He states he was well for two months following this. In the early part of April, 1920, his folks noticed that while talking he would suddenly close his eyes and fall asleep, or he would sit and stare into space. About this time he began to complain of stiff arms and hands, and that they would assume awkward positions. A history of diplopia was elicited that was present only when writing. On July 16, 1920, he was admitted to Lebanon Hospital in the neurological service of Dr. William Leszynsky. A status taken by me this date showed the following: Patient was well nourished, skeletal frame normal, female pubic hair distribution, and scanty hair in the axilla. Skin reaction showed a marked and lasting Sergent's white line. His face depicted no emotional play, his speech was of a monotone character. Standing he presented a semi-stooped appearance, head and shoulders forward, arms adducted at the shoulders, forearms flexed, hands pronated, and the fingers of the right hand, which were tremulous, assumed a cone-shaped appearance. Walking showed that he moved "en masse." Susoccipital tenderness was present. Rigidity of the neck and extremities at this time was more apparent than real.

Eyes: In asking him to close his eyes he showed a coarse tremor, or rather a flickering movement of his eyelids, before they closed entirely. Pupils were unequally dilated, the right more than the left. Both reacted sluggishly to light and in convergence. The right reacted more sluggishly to light. The fundi were negative. Facial innervation revealed left-sided weakness, which disappeared when smiling.

Upper Extremity: Gross motor power is good. Tremor of digits of right hand is present, and is not characteristic of Parkinson's disease.

Reflexes: Radials were diminished bilaterally. Biceps and triceps normal in response. Abdominals, the right less than the left.

Lower Extremity: Gross muscular power intact. The right knee and ankle jerks less marked than the left. Plantar response was normal. No clonus. Superficial and deep sensibility was preserved.

Mentality: He showed no disorder of perception. He was fully orientated. Memory was good, and the content and process of thought disclosed nothing abnormal. Emotionally, he showed some instability. The slightest incident evoked smiles or laughter.

Laboratory Findings: Blood-pressure 100 systolic; 50 diastolic. Blood examination: Hb. 92 per cent. Red blood cells, 5,700,000; white blood cells, 9,200; polys., 68 per cent.; lymphocytes, 32 per cent. Urine examination negative. Blood and spinal fluid showed a negative Wassermann. His spinal fluid came out under pressure. One cell was found to the c.mm.

The temperature was 100° when he entered the service. This lasted ten days. He left the hospital with a normal temperature.

Three months later I again had the opportunity of seeing him, this time on the Neurological Service of Mt. Sinai Hospital, outpatient division.

Judging from some of the progressive symptoms he now showed, one must believe in a subacute or chronic stage, as viewed by Dr. Abrahamson.* In facies, attitude, and gait the symptoms resembled those of the Parkinson type.

Eyes: His eyelids showed a myotonic-like phenomenon, in that when he was asked to open them, it required a number of attempts, and visibly some effort to open them. The pupils were equally dilated, and re-

*Presented before the Neurological Section, New York Academy of Medicine, October 12, 1920.

*The Chronicity in Lethargic Encephalitis, Arch. Neurol. and Psych., October 1920, Vol. 4, p. 428.

acted sluggishly to light and in convergence. A right Moebius was present. When asked to look laterally in a horizontal plane, the phenomenon of a cogwheel movement became apparent. This was inconstant. The fundi were negative. A left facial paresis was apparent, which disappeared on emotional display.

His tongue protruded in the median line, and some thinning was present on the left side. Fibrillation was apparent, together with an occasional myoclonic jerk.

Rigidity was shown in the neck, more marked on the left half of the body. His left upper extremity was held in a Parkinsonian attitude, and there was tremor of the left digits, facial muscles, eyelids, etc.

Reflexes: Knee and ankle jerks were present. Abdominal and cremasteric reflexes were normal. Plantar response was normal. Vibratory sense was diminished on the right side. A marked Sergent's white line was elicited. Blood pressure, 100/50.

The patient fell asleep when left alone. He still showed his mental instability, and in addition slight changes in character and habits. He was not as careful in dress; was shiftless, smoked excessively, and played with children much younger than himself.

This patient therefore presents a chronic progressive condition, affecting the central nervous system, mind and endocrinous system to a lesser degree. The central nervous system shows an involvement of the mesencephalon and basal ganglia. The paleokinetic projection system with its anisotropic disc and muscle plate, and to a lesser degree the static system with its sarcoplastic connection were involved, as shown by posture, rigidity, tonus, and myotonic manifestations.

His emotional instability can most likely be attributed to a perverted or a diminished function of the thalamus. It is interesting to recall at this time the vibratory diminution on the right half of his body. Whether the sleeping phenomena can be attributed to the same organ is still a mooted question.

His change in behavior and slight mental change point to perhaps a toxic involvement of his higher frontocortical cells. His endocrinous system involvement is shown by his low blood pressure, tachycardia, and the marked Sergent's white line. These phenomena point to adrenal implication.

The question arises, is this a residual state, or is there still going on a slow smouldering toxic condition which gives this picture of subacute or chronic process? His condition has progressively grown worse during the past three months.

A PRELIMINARY REPORT ON LABORATORY EXPERIMENTS TO DETERMINE THE VALUE OF CERTAIN AGENTS IN CONNECTION WITH SURGICAL OPERATIONS.

By JAMES T. GWATHMEY, M.D.,

NEW YORK,

AND

E. S. TIBBETS, M.D.,

CUMBERLAND, MD.

THE laboratory experiments briefly detailed herewith were undertaken to determine the value: (1) of warmed oxygenated ether vapor during the operation; (2) of the preoperative administration of sodium bicarbonate; (3) of the combination of these two agents. These experiments were conducted under the supervision of Dr. George Barclay Wallace of the Pharmacological Department of the University and Bellevue Medical College. Between fifteen and twenty experiments were made to determine the comparative value, with regard to

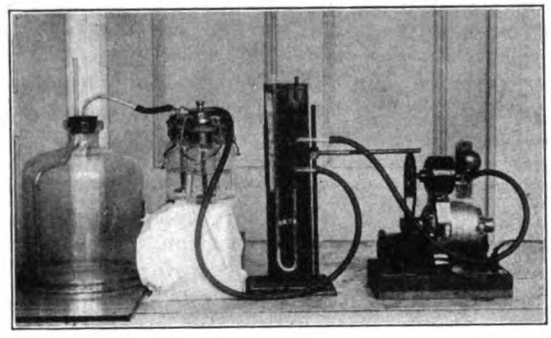

Fig. 1.—Showing (1) the glass bell-jar with stopper through which passes a thermometer, the anesthetic tube, and the escape tube; (2) the anesthetic container; (3) a mercurial manometer, and (4) an electric motor.

immediate safety of life, of warmed oxygenated ether vapor (98° to 100° Fahrenheit) as compared with air-ether vapor at room temperature.

The animal was placed under a glass bell jar (see Figs. 1 and 2), in the rubber stopper of which was a short tube leading from the anesthetic. A glass overflow tube passed through the same stopper and extended to within half an inch of the base upon which the bell-jar rested. The air or oxygen was forced at a fixed pressure of 32 mm. Hg. through a bottle containing ether and then on into the bell-jar containing the animal, the apparatus being so arranged that the percentage of ether in the mixture passing to the bell jar was constant. An additional arrangement allowed any desired temperature of the mixture. The time was reckoned from the commencement of the administration

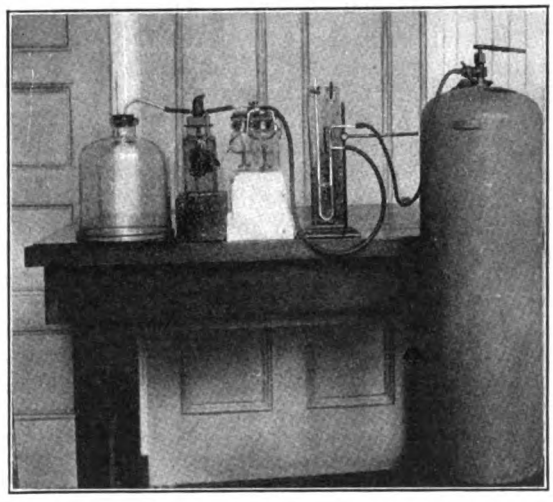

Fig. 2.—Same apparatus as that shown in Fig. 1, except that the heater is placed in circuit between the ether container and the bell-jar; and the oxygen tank takes the place of the electric motor.

of the ether vapors to the stoppage of respiration. The animal was then resuscitated and allowed to run at large for twenty-four to forty-eight hours. After this it was again anesthetized, but in the opposite way (*i.e.* if the first anesthetic was air-ether,

the second was warmed oxygen-ether or vice versa).*

The final results were as follows: Taking an average time for the stoppage of respiration after the anesthesia was started, 72 per cent. of the experiments in which this time was lengthened was with animals given the warmed oxygen-ether mixture; and 28 per cent. with those given the air-ether mixture. In other words, the former was more than two and a half times as safe as the latter. Only one animal failed to respond to resuscitation; this was an air-ether experiment. Two of the warmed oxygenated-ether animals were breathing regularly at the end of twenty-two minutes, requiring no efforts at resuscitation. The percentages just mentioned do not, therefore, and cannot, express the very great advantage as regards life derived from warmed oxygenated ether as against air-ether at room temperature.

These experiments corroborate to a certain extent the experiments made by one of us (J. T. G.) during 1904-1905 in order to determine the value of oxygen, and also of warming anesthetics to about blood temperature (90° to 100° F.) and comparing these results with those obtained from anesthetics administered with air and also at room temperature (65° to 72° F.). While these experiments were crude as compared with the later ones, which were done under proper laboratory conditions, yet they were comparable to each other in their final results.

From the experiments with oxygen as compared with air, and with vapor heated to the temperature of the blood (98° to 100° F.) as compared with room temperature vapors, it was determined that both oxygen and warmth increased the value of all anesthetics—rendering their administration safer without decreasing their anesthetic value.

At the suggestion of Dr. George Barclay Wallace, another series of experiments was conducted to determine the value of sodium bicarbonate in preventing acidosis during anesthesia. This was done in the following manner: Eight pregnant guinea pigs were placed successively under the glass bell-jar, as described in the previous experiments. Four were given a hypodermic of 5 cc. of a 3 per cent. solution of sodium bicarbonate; in addition they were fed 5 cc. of this agent in milk, mornings and afternoons. In the middle of each day the animals were anesthetized for 25 minutes, this procedure being repeated for six successive days. On the sixth day, and while the pigs were under the anesthetic, 2 cc. of blood was withdrawn from the animals' hearts and the same amount of physiological salt solution was injected. This blood was placed in the ice chest and allowed to remain overnight (each specimen in a separate tube). The following day the clot which had formed was removed and the serum was tested for acidosis by the Van Slyke method.

Normal blood shows a 55 to 75 percentage of alkalinity. The experiments showed that when no sodium bicarbonate was given the alkaline loss was approximately the same for each anesthetic (34 with air ether; 35 and 28 with warmed oxygenated ether).

When the preliminary sodium bicarbonate was given, the pigs receiving the warmed oxygenated ether showed a much higher blood alkalinity (.88 and 1.38) than those receiving the air-ether mixture (.54 and .68).

Obviously, the preliminary administration of sodium bicarbonate is of even more importance than the choice between the air and warmed oxygenated ether vapor, so far as acidosis is concerned.

The immediate risk to life is less with warmed oxygenated ether vapors.

40 East Forty-first Street.

*This work, which was begun during the summer of 1917, was discontinued on account of the war.

SOME HISTORY, A THREAT AND ITS FULFILMENT.

By JOHN J. A. O'REILLY, M.D.,

Brooklyn, N. Y.

Chairman, N. Y. State Association of the Medical and Allied Professions; Lecturer in Legal Medicine at the Brooklyn Law School of St. Lawrence University; Assistant to the Department of Nervous and Mental Diseases at the Kings County (N. Y.) Hospital; Member of the New York Bar.

"If you refuse to make operative the Compulsory Health Insurance Bill, if passed, your License to Practice Medicine will be taken from you under the Police Power of the State."

These words, my dearly beloved brethren, are taken from the sayings of the Senator from the Sixth District (Kings) at a meeting of the Eleventh Assembly District Chapter of the Professional Guild of Kings County, held on Oct. 31, 1919, and form the text for our discourse upon the Compulsory Health Insurance and Socialization of Medicine scheme for the political control of the laboring man and the degradation of the medical profession with the Medical Practice (Reregistration) Act as a legislative club to beat the practitioners of medicine into submission or innocuousness.

You note the ministerial type of address? Well, that is for the purpose of introducing you to the new atmosphere which is being developed around Compulsory Health Insurance, State Medicine, the National Socialization of Medicine, and the Medical Practice (Reregistration) Acts so that the smell of un-Americanism which exudes from the officer body of the instigator and propagandist in chief, the American Association for Labor Legislation, may be masked by the odor of mock sanctity which is exhaled by some church organizations which are permitting themselves to be used as propaganda centers by calling conferences in the name of religion and packing them in the interests of the propagandists, and holding them in the home of a moneyed foundation in East 22d Street, New York City, the altruism of which is somewhat tarnished by the fact that the miscalled "welfare" legislation exploited by these Arrogant Associations for Lucrative Legislation (A. A. L. L.) would convert the administrative departments of the State of New York into employment agencies for the schools of philanthropy, sociology, and psychology, maintained by these foundations, whose protégés and graduates have an "urge" to satisfy the "something for nothing lads" at the expense of the goat—the tax-paying public of this and other States.

Before the Senate Committee, at the 1920 hearing on the Davenport Compulsory Health Insurance Bill, the executive secretary of the American Association

for Labor Legislation (A. A. L. L.) declared that he would inaugurate a campaign of education as an antidote to the "poison" which Senator Davenport said "had changed the public mind from an attitude of receptivity for this 'wise' social experiment to one of bitter antagonism." I knew then and I know now that the proponents *dare not go to the people with the facts* any more than the executive secretary dared meet the issues before the Flushing (L. I.) Taxpayers' Association, or Senator Davenport dared meet the issue of cost before the Kings County Young Republican Club. They dared not go and they have not gone to the people with the facts. Senator Davenport's professorial formula before the Kings County Young Republican Club that "the cost would be distributed in increased efficiency and good will" is not argument; it is an insult to the intelligence of the average citizen who *knows* that the employers' cost will be added to his overhead and appear as increased cost of living to be paid by the ultimate consumer, that "dear working person," for the food he must eat and the things he must drink and the raiment with which he must be clothed.

A campaign of education is the one thing the uplifters will not inaugurate because it would be fatal; it simply is not done. Here is the way *they* play the game:

In December, 1919, they staged a "conference" of the proponents and opponents of Compulsory Health Insurance at the Hotel Astor under the auspices of the Sub-Committee on Industrial Relations of the National Republican Club; the conference was presided over by a member of the committee, R. J. Caldwell, a manufacturer of Danielson, Conn., who was *also* a member of the executive committee of the A. A. L. L., and later its president; the proponents were the American Association for Labor Legislation septette, Samuel McCune Lindsay, the then president; John B. Andrews, executive secretary; John A. Lapp, Alexander Lambert, M.D.; Louis Harris, M.D.; Sigismund S. Goldwater, M.D.; and Harold Chamberlain.

The idea was to get the conferees to agree upon a compromise by indorsing the *principle* of Compulsory Health Insurance while damning the Davenport Bill with faint praise, *but*, committing the opponents to the support of *some kind* of a bill and seducing them from the attitude that the "Compulsory Health Insuranse plan is as incapable of constructive amendment as is a rotten egg. . . ." With such a compromise the pro-Socialism group in the National Republican Club could spike the guns of the anti-Socialism group and put across a favorable recommendation of the "welfare" program; the plan aborted because the opponents, of which I was one, would not accept in compromise what they could not subscribe to in justice; it is history that at a subsequent stormy meeting of the National Republican Club they refused to pull the A. A. L. L. chestnuts out of the fire. Senator Davenport introduced his (1920) bill "for educational purposes only"; shortly before the pro forma hearing on that bill the Senator telegraphed a State society leader that the bill would not come out of committee and intimated that the opponents might save themselves the trouble and expense of going to Albany to attend the hearing. This was politics, but it slipped a cog because we knew, as well as Senator Davenport, that he could not drag that bill out of committee with a pair of forceps; the results of the 1919 Assembly elections, in the districts where Compulsory Health Insurance was an issue, indicated public resentment of this waste of the money and man power of the State. When that pro forma hearing was held there was the usual (and expected) line-up of the proponents,—the A. A. L. L., the Women's Trade Union League, the New York Federation of Labor, and the Y. W. C. A., *and* the opponents, who had been advised to disregard telegrams of assurance in the light of the broken promise of March 19, 1919, that Senator Davenport would not permit the bill to come out of his committee "until and unless the sacred relation of the doctor and his patient was safeguarded"; history has it that the (1919) bill *did* come out and that Senator Davenport led the insurgents who made its passage in the Senate possible: The 1920 opposition did not take the form of 500 medical men from all parts of the State presenting dignified and elegantly phrased resolutions of protest, as in 1919, but of a small group of men and women who represented the organized opposition of the medical, dental, and pharmaceutical professions who had *gone to the people with the facts* and could "point with pride" to the fact that the people "viewed with alarm" this hysterical legislation and had "spoken their minds" with definiteness at the polls in November, and the leaders knew it was not politics but civics they were up against.

History tells more—13 out of 13 bad public health bills went to the scrap heap this year.

Then the propagandists re-formed their lines; taking a leaf from the book of "Aunty Anderson" they got busy with the church organizations and the pulpit of a church in Flatbush was given over to the discussion of the boon which welfare legislation, including Compulsory Health Insurance, would be to the "dear people." A little later the Research Department of the Commission on the Church and Social Service of the Federal Council of the Churches of Christ in America (some mouthful) held some *conferences*. I attended the first and found there one other anti, Dr. Delphy, and lined up in favor of this "wise social experiment" was the A. A. L. L. quintet—John B. Andrews, John A. Lapp, Harold Chamberlain, Louis Harris, M.D., and Professor Devine, then of Columbia and later the editor of the *Survey*. The meeting was held, not in a church or a meeting house as would befit a church organization, but in the home of the Sage Foundation, and a questionnaire was distributed:

1. What is the extent of sickness now *unprovided* for by private means?
2. What experience with Health Insurance is looked upon as a demonstration of *success?*
3. *Why* are so many physicians opposed?
4. What effect would Compulsory Health Insurance have upon *commercial insurance?*
5. What are the *most* disputed points in the Davenport Health Insurance Bill?
6. *Is there* any alternative proposal?
7. Who are the beneficiaries?
8. Should small tradesmen as well as industrial workers, *etc.*, be included in the benefits?
9. What would the measure cost the State?

10. Should *industry* carry the whole burden?
(*Italics* are mine.)

Familiar, isn't it?

Then, to show how broad and liberal is the spirit of these ultra-altruists, the Roman Catholic Church was brought into the limelight as indorsing Compulsory Health Insurance, *although* the official pronunciamento of the Bishops' Council (Reconstruction Pamphlet No. 1, January, 1919) expressly says (page 18): "Any insurance scheme, or any administrative method, that tends to separate the workers into a distinct and dependent class, that offends against their domestic privacy and independence, or that threatens individual self-reliance and self-respect, should not be tolerated."

But the A. A. L. L. had another quiver to its bow: When it began to dawn upon these people that there were minds in the State which were capable of recognizing *inverted economy*, they looked about for an alternative proposal (item 6, Questionnaire, *supra*) which would accomplish the same result in berths for those psychanalysts, sociologists, philanthropists, etc., etc., and they evolved *State Medicine.*

The compulsory health insurance propaganda of 24 cents per week per employer and employee as premium; the free choice of (panel) physician; the supervision of medical care and compensation by the County and State Medical Societies (under Sec. 12, God save the mark!); the trifling cost of State supervision (a beggarly $22.32 per average man) or $90,000,000 for 4,000,000 persons as an *annual deficit;* the boon of "extension of benefits" (which would penalize a laboring man for striking to better his condition.) . . . All these things had been measured at their full value by the people of the State and promptly and effectually repudiated and rejected. . . . Therefore, they grasped the *group medicine* which decent, self-respecting, devoted doctors have developed for the advancement of science and the betterment of their fellow man, and they began playing it up as *State medicine* and they advanced the specious propaganda that: "To get the boys back to the farm we must have a hospital and a health center in every agricultural district and we must centralize the agencies of healing."

This looked mighty good to them and they expected the people would rejoice and be glad to try "this wise social experiment" and be willing, a little later, to stand for the national socialization of medicine with a secretary in the cabinet and political control of all the agencies of healing, down to the horse which draws the ambulance.

They know and you know and I know that a measure confined to the agricultural sections would yield no appreciable results in jobs for the graduates of their schools of philanthropy, sociology, and psychology, so they slipped in a few clauses which would extend the "benign" influence of this "forward looking advance agent of the Brotherhood of Man" to the cities of the first class *where the pickings are.*

Experience has been a good teacher; when we analyzed that bill (Sage-Machold, Senate bill 1533) we found the framework of one of the most gigantic political machines the State has ever contemplated; beginning with a State Superintendent of Health, taking his appointment from a partisan Governor and running down through health officers, medical boards, doctors, dentists, druggists, nurses, etc., all taking their appointments from and through boards of selectmen, boards of supervisors and boards of estimate; all feeding at the public crib with the sick citizen as the victim of demoralized agencies of healing sure of their checks at the end of the month provided they "deserved well of their party." Apart from this plan for destroying the morale of the profession of medicine stands the scheme for securing the control of existing hospitals, laboratories, etc., or building others, with all the attendant opportunities for graft and saddling upon an already overburdened public the tremendous waste of the money power of the State.

The decent doctor knows the value of group medicine conducted and controlled by medical scientists; he knows that all over this State are hospitals and laboratories equipped for advanced scientific diagnosis which would enable a doctor to acquire a greater grasp of his patient's case, the patient to reap the benefit of early and complete analysis, and the State to share in the advantage of the rapid restoration of the sick to health and usefulness; doctors feel that these advantages should be brought within the reach of the moderately paid workman because they know that the poor and the rich have these advantages anyway; they want it to be possible for a doctor to send his patient to any such institution and to secure what analysis he wants and the patient needs without being *penalized* by coming under the care of a *panelized* doctor to whom, under the circumstances, he can not be other than a "case." The medical profession can and should work out this problem and they are amplifying these opportunities every day: The death rate in the United States (14.2), which is the envy of every civilized nation, is speaking evidence of this constructiveness. They know, deep down in their souls, that to make this function of medicine a pawn in the game of politics under a Sage-Machold State Medicine Bill (Senate Bill 1533) with the sick citizens *cattleized* and the professional philanthropists, sociologists, psychanalysts, and false doctrinaires subsidized, means rotten medicine, and they have the courage of their conviction to go to the people with the facts and to say that they can not and will not help to make such a wasteful and vicious policy operative. *Then comes the threat* and the attempt at fulfilment thereof.*

All through this vicious abuse of the intellects which God gave those university, magazine, parlor, and gutter agencies of unrest, they recognized that the medical professions constituted a force for order which was in sympathy with the principles, traditions, and institutions of this nation and opposed to the doctrines of the "worshippers at the shrine of something else than Americanism" whose high

*Lest some wise one attempt an anti-climax by telling you that there was a State Medicine Bill and a Medical Practice (Reregistration) Bill in the 1919 Legislature, let me tell you that it antedates even that; it goes back to the 1901 (Paris) Congress of the Labor Internationale, designed, inspired, financed, and controlled by the Imperial German Government for spreading the propaganda of *Kultur* for the purpose of breaking down the social, physical, and economic forces behind the lines in the countries which it was intended, later, to subjugate.

priests these professorial agitators are; the refusal of the devoted and conscientious men and women of medicine to help make operative such destructive measures and policies was an "insurmountable obstacle" which must be met by the "irresistible force" of coercion to beat them into submission or render them innocuous by driving them without the pale. To make it a misdemeanor for any doctor to treat any patient save as part of this political machine would be so raw that even the fossilized, ultra-ethical, and sacrosanct among the practitioners would wake up; besides, it would bruise the toes of the false medical leaders upon whom they counted to play the County, State, and National Medical Society politics in their interest; something subtle and seductive of the "poetic" doctor was the high card; something that would appeal to his jealousy of the high standards of his profession and the scope of service to his kind—so the "mountain labored and brought forth this *"gnat"*:—

"The annual reregistration of doctors will enable you to secure a *medical census* and locate the illegal and unlawful practitioners and insure their punishment by transferring the prosecution of such cases from the district attorneys of counties to the Attorney General of the State."

Great stuff, that! We need a medical census just as much as a cat needs two tails; the State is spending a lot of money, through the Secretary of State, the board of regents, the health department, the attorney general's office, etc., etc., to make and keep proper records of licensees and vital statistics and the Secretary of State's office collates and checks them all up, while the county clerks and the local health departments lend a hand. If all these agencies have "fallen down on their job," the United States Government has just completed a Census which they may use to bring the information up to date.*

Just press your "common sense button" and estimate the sincerity of these propagandists and their dupes in the light of the fact that that same Medical Practice (Reregistration) Act, if passed, would have let down the bars to unbridled exercise of birth control by that rotten type of doctor who places money before honor and waxes rich on the practice of feticide and infanticide and the teaching of contraception, and whose only real check is Sec. 170-d of the Public Health Law, which provides for the revocation of his license if he violates the provisions of Sec. 1142 of the penal law, except in the exercise of good faith, of which his medical peers, and not a lay jury, shall be the judge. The Kenyon Bill (Assembly Bill 840), Medical Practice Reregistration Act, eliminated that Sec. 170-d to make place for the annual reregistration of the doctors of this State subject to the discretion of the licensing board (an administrative department), and without the right of appeal to the judicial branch of the government upon the merits of the case, leaving a doctor a mandamus proceeding as his only recourse, with the absolute certainty of that writ of mandamus being denied under the ruling decision on the scope of the *police power of the State* (Dr. Dent vs. State of West Virginia, 129 U. S. Reports, page 114, year 1889). If you have any doubt whatever of the sureness of my foundation for this message to you in warning of the real purpose of the Kenyon Bill (Medical Practice—Reregistration Act) ask some lawyer friend or patient to read the bill and the decision in the case of Dr. Dent in the light of the threat with which I open my story and in consideration of the fact that on Oct. 31, 1919, and now there was not and is not a single New York statute under which that threat could be made good.

Read and have him read Sec. 169 of that Kenyon Bill in consideration of the fact that there are probably not five doctors, *graduated prior to* 1895, who have not completed their registration during the past twenty-five years or whose registration contains a defect which requires remedying *at this time* through the resurrection and revivification of an enabling clause necessary in 1896 but entitled to remain dead in 1920.

Then read and have your lawyer friend read the whole bill and see if he can find a single if, and, but, or provided, upon which he could predicate a clear right to a decision in your favor on such a mandamus proceeding in the light of the decision in the case of Dr. Dent, which would be a *sine qua non* for the exercise of equity in your behalf if reregistration were denied you. . . . Ask your lawyer friend what effect the equitable maxim—"He who will not when he may may not when he will"—would have upon your mandamus proceeding when it was shown that you and your brothers in the profession of medicine were guilty of laches in disregarding such warnings as this and, instead of fighting this vicious legislation with all the power of your personal influence among your people, the voting public, contented yourself with "Why, Doctor, they couldn't pass such a bill; it would be unconstitutional." A lot of Americans said that about prohibition and rolled over and went to sleep again; when they awoke they found it was the law and the courts were powerless to change or modify the conditions.

The theory that this bill would corral the illegal and unlawful practitioners and charlatans by transferring the prosecution from the district attorneys of counties to the attorney general of the State is

*Assemblyman Kenyon, the introducer of the Medical Practice Reregistration Bill, quoted the State Medical Society as indorsing his bill. Despite the fact that it was killed through the influence of the rank and file; despite the fact that it would, if passed, make the unbridled exercise of birth control lawful and moral and the State Society its sponsor, through the elimination of Section 170-d of the Public Health Law at the behest of the birth controllists, nevertheless, the council of the New York State Medical Society on May 22, 1920, "directed the chairman of the Committee on Legislation to introduce the Medical Registration Bill at the next session." The rank and file must decide whether this is to be taken as rank ignorance of the capacity for coercion which this bill contains, or rank, insolent disregard of the wishes of the practitioners, or the rights of the people to have their agencies of healing safeguarded rather than subordinated. Said a state leader to me: "If you attempt to defeat the Medical Practice Reregistration Bill you will be crucified." Even so; it must be defeated in 1921 or the ruling decision on the police power of the state—Dr. Dent *vs.* State of West Virginia, United States Supreme Court Reports 129, at page 114 (year 1889)—will be made applicable to the Laws of the State of New York as it is not now and cannot be under already existing laws, the threat of October 31, with which this article opens, to the contrary notwithstanding.

neither warranted by the facts nor necessary under the law.

If you can find me a single district attorney in New York State who chooses the violations of the Practice of Medicine Act as the channel which to manifest his infidelity to his oath of office, I will show you existing law and precedent for the attorney general of this State superseding that district attorney by a special deputy attorney general empowered to act in any case in any county in which the State, as such, is a party in interest; and if the State be not a "party in interest" in maintaining the integrity of the agencies of healing, then the people of this State would like to know it.

Have your lawyer friend read that bill in the light of the status of Section 169, with its amendment, as new law which provides for the indorsement without further examination of the diploma of a doctor graduating *prior* to 1895 and search the provisions of that bill for reregistration of a diploma without further examination if the applicant graduated *after* 1895 and the reregistering body saw fit to exercise its discretion against one, for example, who was unwilling to "help make operative" a compulsory health insurance law, or a State medicine law, or a birth control law, or a national socialization of medicine law.

The propagandists have an "urge" to safeguard and purify the practice of medicine and rid it of charlatans, have they? Then why in the name of common sense and civic decency do they exploit a drugless therapy bill (Carroll), Senate Bill 582, which would legalize every form of charlatanism known and to be known. Read it—here is Section 1, Article 1:

"The practice of drugless therapy, which is a system, method of science of healing disease without the use of drugs or medicines of any kind, using massotherapy, mechanotherapy, electrotherapy, hydrotherapy, naturopathy, chiropractic, napropathy, neuropathy, dietetics (food science), suggestive therapeutics, magnetic healing, vibrotherapy, zonetherapy, *or any other drugless methods that hereafter become known or in use.*"

Need I say more to awaken you to a realization of the fact that by virtue of your training and education and experience you are one of the best qualified teachers in society, and by virtue of the intimacy and sanctity of your relation with your patient you are one of the most forceful teachers of society, and that it is your solemn duty to your order, your family, and your State to use those faculties by going to your people, the voting public, *with these facts*, in their homes and on the street, in public halls and in the lay press, by exhortation and in debate, and putting it up to them to say by their votes whether they want their agencies of healing made part of a political machine through compulsory health insurance, State medicine, the national socialization of medicine; whether they are willing to have their agencies of healing forced *into* service as panelized, impersonal practitioners or forced *out of* the practice of their profession through a Medical Practice (Reregistration) Act: Go to the people with the facts! An informed American people never went wrong and never will.

405 UNION STREET,
BROOKLYN, N. Y

GALVANO-PALPATION.

A METHOD OF DETECTING THE PRESENCE OF INTERNAL DISEASES BY MEANS OF THE GALVANIC CURRENT.

BY MAX KAHANE, M.D.,
VIENNA.

GALVANO-PALPATION is a method of testing the sensory and vasomotor nerves of the skin. It consists in the application, for short intervals frequently repeated, of a needle-like anode electrode, as sharply pointed as possible, to the part of the skin that is to be examined, while the indifferent electrode (the cathode) is applied to some other part of the body, *e.g.*, the palm of the hand.

The mode of procedure is as follows: The patient holds the large cathode electrode in one hand, the very sharp-pointed anode electrode in the other, and then the slightest possible current is turned on. Abnormal reactions are registered and established only if the very weakest current is employed; if a stronger current is employed it will not accomplish our purpose, because it is diverted toward the organ to be examined. For the examination of the cerebral nerves, to see if a neuritis is present, *e.g.*, the trigeminus, the vagus, the accessorius, and for the examination of the cervical portion of the gangliated cord, and of the thyroid body, one should employ not more than 0.5 milliampères; for the nerve roots and the peripheral nerves, about 1.0 milliampères; for the thoracic organs, 1 to 1.5 milliampères; and for the abdominal organs, 2.0 to 2.5 milliampères. The desired current having been turned on, the physician takes the anode electrode from the patient's hand and applies it numerous times with a slight tapping motion to the spot to be examined.

Essential conditions for success, for a reliable diagnostic result, are the following: (1) the examining electrode must be the anode electrode; (2) the anode electrode must have a very sharp point, so as to assure a maximum of current density, and (3) the application of the current must be direct and frequently repeated, and any escape of current must be avoided.

A negative result does not warrant a negative conclusion! Diagnostic value is to be attached only to a positive reaction. The galvanic current acts on the sensory and vasomotor nerves of the skin. The sensory reaction consists of a scratching, pricking or burning sensation, and the vasomotor reaction of a reddening of the skin. The intensity of the reaction varies with the character of the lesion and is of diagnostic import. The vascular reaction is the more important because it is objective; as a rule the sensory and vasomotor reactions run parallel to each other, but there are cases in which one is more marked than the other.

The diagnostic importance of galvano-palpation consists in the fact that the cutaneous vasomotor and sensory reactions are of a secondary nature, being dependent on internal diseases, and that topically the reaction spots correspond to the site of the disease. Thus, for example, in an ulcer of the stomach the reaction phenomena (reddening of the skin, etc.) will be strictly limited to the area of skin over the ulcer, and there will be no reaction phenomena whatsoever elsewhere. A third point of great importance is this: the intensity of the

reaction is proportional to the intensity of the irritation or inflammation in the subjacent tissue or organ, and consequently we may gain information as to the progress of the disease by studying the character and intensity of the reaction at regular intervals.

The tissues and organs that lend themselves to diagnosis by galvano-palpation are as follows: on the head, the outlets of the trigeminus, the nose, the sinuses, and nasal cavities; on the neck, the vagus, the accessorius, and the sympathetic, the larynx, the thyroid gland, the cervical roots and the brachial plexus; in the thorax, the lungs, the heart, the aorta, and the dorsal roots; in the abdomen, the superficial portion of the liver, the gall bladder, the anterior wall of the stomach, the large intestine, the appendix, the kidneys, the lumbar and sacral roots; on the extremities, the bones, joints, muscles, peripheral nerves (as far as they are directly under the skin).

A circumscribed reaction over the thyroid gland is an important symptom of hyperthyroidism and can be elicited even with a current of 0.3 milliampères. The anterior wall of the larynx lends itself easily to galvano-palpation; in tuberculous laryngitis there can be elicited a very intense reaction over the seat of the lesion. In thyroidism and in cardiac neuroses we get a strong reaction over the manubrium sterni. In aortitis we get a very characteristic reaction, *viz.*, a circumscribed redness between the manubrium and the corpus sterni at a spot corresponding to the left half of the transverse aorta and the beginning of the second rib (left). Topographically this spot corresponds to the superior cardiac plexus and the inferior margin of the aortic arch.

Galvano-palpation is of special value in those cases of abdominal disease in which the patient's statements are of no value as aids to the localization of the malady. In such cases we can always rely on the vascular reaction. Thus, for example, if a patient complains of pain in the region of the appendix, whereas galvano-palpation elicits redness over the gall-bladder, we may be certain we are dealing with an affection of the latter viscus. It is interesting to note that in cases of spastic constipation we find galvano-hyperesthesia (*i.e.*, a positive reaction) in the right iliac fossa, and in atonic constipation in the left.

It is one of the great advantages of galvano-palpation that it can be applied even in cases of very acute inflammations without doing the patient any harm. Naturally, it may also be employed in the case of a person who may have lost consciousness and even in children.

In cases of neuralgia the method is of great value inasmuch as it enables us to decide whether we are dealing with an affection of the nerve roots or of the peripheral nerves themselves. Bones, joints and muscles are also suitable objects for examination. I have been enabled by this method to prove that "muscular rheumatism" is not a muscular neuralgia but a circumscribed myositis.

The method is perfectly simple, can be easily and quickly applied by anyone having the necessary apparatus (especially a sensitive galvanometer and a sharp anode electrode), and yields valuable results, when the reaction is positive.

PARTIAL ASPHYXIATION IN AN INFANT, RESULTING FROM THE INHALATION OF A DUSTING POWDER.

By LOUIS FISCHER, M.D.,

NEW YORK.

THE following case seems to deserve publication on account of its rarity and of the success of the treatment employed:

R. M., seven months old, was seen by me in consultation with Dr. S. M. Clurman. He was a breast-fed infant, gaining in weight. At the time of the present illness he weighed about twenty pounds. According to the history given he was left to play with a box of dusting powder consisting chiefly of stearate of zinc. When discovered by the mother his mouth was filled with powder. Twenty-four hours later I was called to see the infant and found the respirations 60, pulse 160, and temperature 99°. There was marked dyspnea, also retraction of the chest. The breathing was labored, not croupy, but a stenosis of the air passage existed.

Examination of the thorax revealed crepitant râles—diffused on both sides, also a complete absence of the respiratory murmur on the left side of the lung, fair breathing on the right side.

Deficient oxygenation existed, as was apparent by the cyanosis of the lips and ears. There was no evident dullness on percussion. The alæ nasi were very prominent. There was superficial breathing—very labored. We expected some assistance from the *x*-ray picture which was taken by Dr. Abrams of Brooklyn. It showed a normal thorax—no abnormality, no pathological lesions discernible.

The case was seen frequently by Dr. Clurman. The symptoms increased hourly, so that a grave prognosis was made. Steam inhalations were used with no apparent benefit. On palpating the epiglottis and larynx I was able to bring away considerable powder which adhered to the adjacent parts. Emetics were frequently given, but did not seem to dislodge the foreign particles of powder. There was an occasional cough. On the following day the respirations rose to 74, pulse 164, temperature 102.5°. Pneumonia was suspected. To be prepared for all emergencies Dr. Charles Goodman was called and requested to be present should grave symptoms demand a tracheotomy. After studying all symptoms carefully and considering catheterization of the larynx, intubation, and possibly, tracheotomy, it was decided to use stimulating expectorants, chiefly senega, and thus dislodge by mechanical means as much foreign material as possible. This measure proved successful. The expectorant was given. The symptoms gradually subsided, and the infant made an uneventful recovery within three days.

33 WEST SEVENTY-THIRD STREET.

A Fourth Symptom Added to the Triad of Hutchinson.—Cantonnet adds hydrarthrosis to the triad of Hutchinson—notched teeth, deafness, and interstitial keratitis—as evidence of hereditary syphilis. He thus makes it a tetrad. Cantonnet is an ophthalmologist, and as these practitioners see these cases first because of the keratitis (or perhaps since many of them treat the ear because of the deafness) he and his colleagues are likely to note the presence of any other stigmata. The hydrarthrosis is painless and hence easily escapes observation. Statistics of Clutton showed hydrarthrosis eleven cases, keratitis ten cases, notched teeth five and deafness two cases. Puech in one material saw twenty-seven cases of keratitis, eleven hydrarthroses and five auditory cases. Fouquet saw eighteen keratitides, eleven hydrarthroses, two deafnesses, and Merlier five keratitides, four hydrarthroses, and one deafness. Hence hydrarthrosis appears to be more common than notched teeth and deafness, but less common than keratitis. The joint symptom may be mono- or polyarticular. It may often be found by searching for it, and quite frequently a case believed to have been of traumatic origin will be found to occur in a heredosyphilitic.—*Le Bulletin Médical.*

MEDICAL RECORD.

New York, December 18, 1920.

DIABETES INSIPIDUS.

WE took the opportunity a few weeks ago to call attention in these columns to some of the features of diabetes insipidus. It seems worth while at this time to point out some of the more recent studies which have led, if not to a definite theory of the pathogenesis of the disease, at least to a clearer conception of some of the controlling factors in instances of the condition which are apt to come to our notice. The subject has been reviewed by J. Bauer and B. Aschner (*Wien. Archiv f. inn. Med.*, 1920, i, 297), who have carefully studied several cases especially in regard to the manner in which they react to the injection of pituitrin. Several reliable observers had already determined that the injection of pituitrin into a patient suffering with diabetes insipidus results in a remarkable diminution in the amount of urine excreted and an increase in the specific gravity. This reaction is seen in the majority of the cases of this disease, but in some few it is very slight or even absent. It depends upon some substance in the posterior lobe of the pituitary gland and perhaps also to some extent in the pars intermedia. The dependence of diabetes insipidus upon lesion of the hypophysis is not exactly clear cut, for removal or complete destruction of the posterior lobe or of the whole gland does not result in the typical polyuria and careful microscopic examination of the gland in cases which have been so studied have failed to show any recognizable lesion. Nevertheless some relationship appears to exist. It is difficult to say whether this reaction can be associated in any way with the remarkable effect of lumbar puncture in one or two instances of the condition. Drainage of the cerebrospinal fluid brought about a temporary improvement of the symptoms in one instance and in another apparent cure. These authors recognize these difficulties and are inclined to believe that the influence of the hypophysis is exerted indirectly through the central nervous system and possibly also through the circulatory system.

Three ways are suggested through which diabetes insipidus may establish itself in the body. In the hereditary type of the disease there is apparently a primary anomaly of the kidney, in so far as its inherent nervous apparatus is concerned. In some instances it appears to depend upon a disturbance in the centers in the floor of the fourth ventricle of the brain. These are the ones in which the reaction to pituitrin injections is most striking. Occasionally the disease seems to result from a disturbance in the correlation of the "thirst perception center" and the diuresis center, and in these cases it makes no difference whether the primary irritation of the thirst center results from increase in the concentration of crystalloids in the tissues or whether it is purely psychogenic. The result is the same. They also point out that the discussion as to the importance of primary polyuria or primary polydipsia is of no value, for the two are so closely linked together that either may result from the other. Furthermore, the lack of concentrating power of the kidney may either cause or result from a polyuria.

It is readily seen that the problem of diabetes insipidus has not been solved, but it must be admitted that some progress has been made in that direction. Nor must the reader despair if there seems a tendency to add still another pathological condition to the long list of troubles now blamed upon the endocrine system. The essentially nervous foundation of the disease seems fairly well established, and the next ten years will see more rapid advance in our information than the last ten.

TRUE AND FALSE DYSPEPSIA.

THE term dyspepsia signifies a disturbance of the gastric functions. Therefore, it is a term which designates a functional change and not a morbid entity. When we say dyspepsia we do not imply that the functional disturbance is in any way related to a change in the gastric mucosa—Hayem and Lion's theory of gastritis—or that there is a morbid change in the nervous system controlling the gastric secretion—Leube's theory of nervous dyspepsia. So far as a functional disturbance of the stomach is concerned, dyspepsia involves three gastric functions, namely, the secretory function, and the functions of sensibility and motility, one of these functions being more involved than the other two. Besides these true dyspepsias which imply some functional change of the stomach—changes of the sensibility, motility, or chemism—there exist false dyspepsias in which the functions remain absolutely normal, but the subject, being a psychopath, believes that he is suffering from some gastric disease.

The essential characters of these false dyspepsias consist, firstly, in an absence of any real disturbance of the stomach that can be clinically detected by radioscopy and chemical examination of the gastric secretions; secondly, by the presence of very marked nervous or psychic disturbances. In the statistics published by the late Dr. Déjerine and those of Dubois, of Berne, these false gastropathies represent the majority of cases, while Le Pannetier, working at the department for diseases of the digestive system at the Hôtel Dieu in Paris, found, on the contrary, that this syndrome was rarely present. Le Pannetier partially explains this difference in the

statistics by the fact that several true gastropathies, developing in a neuropathic subject, give a peculiar character to the affection which causes it to resemble the false gastropathies. In order to make a precise diagnosis the clinical examination must be completed by a study of the gastric chemism and a radioscopic examination of the stomach.

The diagnosis of a false dyspepsia—a diagnosis that exclusively implies resort to appropriate psychotherapy—should be made with the greatest reserve and after having examined the stomach thoroughly in order to eliminate any organic lesion such as ulcer, cancer, or gastritis, an organic dyspepsia. False gastropathies may change into true gastropathies by various mechanisms—the mechanism of insufficiency of the nervous system on the secretion, mechanism of inanition, or mechanism of drug intoxication.

The term nervous dyspepsia leads to confusion, and under this term should be distinguished: Firstly, dyspepsias of alimentary origin, toxic, etc., having a more or less marked reaction on the nervous system. Secondly, dyspepsias due to a change in the nervous system of the stomach, sympathetic or bulbar. Doupault and Leube understand nervous dyspepsia in this light. Thirdly, the psychogenous dyspepsias. Consequently it is evident that the term nervous dyspepsia is a misnomer and should be discarded from text-books.

The treatment must be directed against the causative factors of the dyspepsia. In true functional dyspepsias the treatment should correct the underlying pathological changes. When the psychic functions are disordered the dyspepsia will be of the false variety and therefore the treatment is to be directed to the cure of the neuropathy or pyschopathy presented by the patient.

THE PROPHYLAXIS OF ENDOCARDITIS.

IN the *Prescriber* for November, 1920, Dr. G. Arbour Stephens gives some original views on endocarditis and its treatment. He points out that for none of the diseases in which this condition is liable to occur—rheumatic fever, scarlet fever, tonsillitis, pneumonia, cancer, gout, diabetes, and Bright's disease—is there any specific treatment, and that consequently treatment is restricted to preventive measures. He defines endocarditis as an exudation disease, as is evidenced by the vegetations, which are composed of elements derived from the blood. The next stage in the development of the theory is that the disease in which endocarditis occurs is an exudation disease, and as an exudation disease is that condition in which the calcium content of the body is reduced below normal, the obvious treatment is to increase the calcium content by appropriate dietetic measures, that is, if the theory be correct. Stephens insists that the diseases mentioned occur more frequently in those whose calcium content is low and, moreover, draws attention to the point that the greater tendency to endocarditis in the young, when the calcium metabolism at dentition and puberty is under its most severe strain, must be taken into consideration, as well as the fact that heredity probably plays a part in the causation of most of these diseases. Heredity, like pedigree, is almost synonymous with bone, the great lime-containing organ, and apart from a mere tendency, the bad feeding habits of the mother are readily indulged in by her children.

If then these diseases are, as Stephens says, of the "exudation class," due to a lowered calcium content, and also to a perverted or acid appetite, the only rational way of dealing with them is by considering and modifying the food supply of the people. Clean, healthy food, including a pure milk supply, fresh laid eggs, and home-made cheese, should be the staple articles of diet, rather than the over-salted bacon, badly cured fish, and can-preserved food which seem to appeal to the appetites of to-day. Even if Stephens has somewhat exaggerated the importance of the calcium content of the body in the diseases he has referred to, there is no doubt, as Dr. Aulde in this country so eloquently argues, that a low calcium content is prejudicial to health and indeed signifies an actual condition of ill-health. The common-sense treatment of the condition and the preventive treatment of certain predisposing diseases consist almost wholly of dietetic measures.

Others might take to heart, quite as much as the British, Stephens' strictures on the character of our food supply. All over the world to-day canned, preserved, and cured food is consumed to an enormous extent, largely because of the necessities of transportation. Such food is of course better than none, and by it thousands in central and eastern Europe have been kept from starvation, but it is not suitable for a staple diet, and every effort should be made in the war-devastated countries to encourage the cultivation of fresh food, both vegetable and animal. In the meantime supplying the lime deficiency artificially, as recommended by Aulde, would be indicated.

THE RICH BABY AND ITS KEEPER.

THE family possessing simultaneously money and babies (such families undoubtedly do exist) will in practically every instance be found also to possess a nurse. The nurse may be "practical" or she may be just a maid; but she takes care of babies—ergo, she is a nurse. She comes highly recommended, she requires one day a week off, father pays a good round sum for her services,—ergo, she is a "high class nurse;" she can be trusted.

Unless the general practitioner has a remarkable monopoly of the family's good graces, a "baby specialist" is employed, especially if the baby is artificially fed. The specialist arrives, gives ideal directions for care and feeding, and departs, rejoicing in his high-class baby. Sooner or later he may be commanded to return. He receives a cold greeting; and finds the reason in a pale, sickly baby who has rapidly lost weight. He is in imminent danger of being "fired," and of being deprived of as many patients as this family, at least, can contrive to alienate from him.

How often does this syndrome indicate a lesion not in the pediatrist, not in the baby, but in the irate mother herself. She can afford to employ someone whom she thinks she can trust, and who promptly goes her own pseudo-pediatric way unmolested except for occasional visits from members of the family for the purpose of fondling their baby (who may be getting less care, or worse care, than their pediatrist's poorest clinic baby). How often does the pediatrist come upon some "old and trusted nurse" who must sneak "a little castoria" or "a little paregoric" into the baby's unsuspecting bowels.

Such cases of unwary mothers and incompetent nurses are fortunately relatively infrequent. But they occur often enough to warrant constant vigilance on the part of the medical man in change of the rich baby. He should bear in mind that the severe cases of (preventable) athrepsia are by no means limited to the poorer classes; that he must be strict in his insistence on the right treatment, whether his patient be rich or poor, though the former often require more punctilious watching of the step when a scolding is contemplated!

The health of the baby is purchasable. But no social order has yet been devised which permits a mother to delegate responsibility for her baby's well-being.

A Bill for the Protection of Infancy and Maternity.

The Children's Bureau of the United States Department of Labor has just sent out a bulletin urging support of a bill asking Federal aid in the protection of infancy and maternity. The statistics of the Children's Bureau show that in 1918 some 23,000 mothers died in childbirth in the regisration area of the United States and nearly a quarter of a million babies died under one year of age. These statistics show that it is safer to be a mother in fourteen important foreign countries than in the United States. During the past twenty years the typhoid fever rate has been cut in half, the tuberculosis rate markedly reduced, the diphtheria rate reduced more than one-half, but there has been no decrease in maternal deaths. It has been shown that 80 per cent. of the mothers have received no advice or trained care during pregnancy. In the country as a whole there has been practically no organized effort to meet the need for instruction in prenatal and infant hygiene and for trained care during pregnancy and confinement. This problem is not local or sectional, but nation-wide. Federal action is therefore urgently needed. The bill for which the Children's Bureau is urging support offers a practical method of cooperation between the Federal Government and the States. Such Federal aid would stimulate the rapid extension of work which is necessary to prevent further loss of life and health; it would make possible the coordinating and supervising of local work; it would provide facilities in those areas where the local funds are least able to provide them by making State and Federal appropriations available to supplement local resources, and, in general, it would further the nation-wide interest in the protection of maternity and infancy, and help it to find prompt, effective and permanent expression.

Nevo-Encephaloma.

This peculiar neoplasm is described by Audry in the *Annales de dermatologie et de syphiligraphie*, i, 8-9. A case is reported in detail. As cerebral tissue in an embryonal state is associated with ordinary nevus tissue the condition may be regarded as akin to a small, atypical encephalocele, spina bifida, and similar conditions. The location shows that the brain substance emerged as a result of incomplete closure of the nasolacrymal fissure. The types of tissue are not intimately mixed for the cerebral component lies beneath the ectodermic structures. In the reported case the patient was a child aged three years with one tumor on the vertex and another at the upper third of the right eyebrow, both formations being congenital. The latter of the tumors was clearly a nevo-encephaloma, but the mass on the vertex was a serous multilocular cyst, the significance of which was not apparent. Although the child was healthy and generally well developed there were several minor stigmata about the head and face. The forehead was bulging and somewhat asymmetrical. The left eyebrow was at a lower level than the right, and the external extremity of the latter seemed pulled up strongly. The space between the tumor and the eyelid was the seat of fine, short, and sharp hairs directed like the eyebrow hairs. There was an ogival palate but dentition was normal and heredosyphilis could be excluded. Clinically the tumor would have passed readily as a wen. It was removed along with the other mass. There was no suggestion of malignancy.

Progress of the Warfare Against the Pestilences of Eastern Europe.

A French Red Cross Report, digested in *La Presse Médicale* for Sept. 15, 1920, xxviii, 65, gives a sketch of the epidemic situation in Eastern Europe. Beginning with Eastern Galicia, it is stated that typhus has recently shown a recrudescence evidently as a new contamination from Lithuania, Volhynia, and Podolia, where a quarter million cases are believed to exist with a mortality averaging 25 per cent., which means the death of 25,000 each month. From this region Eastern Galicia and Eastern Poland are constantly menaced, and the battle ground to fight the plague must be along this frontier. On the other hand Checo-Slovakia is almost free from typhus, while smallpox, although nearly 1,500 cases have been reported, is running a benign course. In Poland only the Eastern portion is afflicted with typhus, and smallpox and dysentery, while they occur, are not menacing enough to cause alarm. In Roumania the situation is well in hand; in Transylvania it is encouraging. The regions included in the limits of Jugo-Slavia show a certain amount of typhus, but less than 300 cases a month for the entire realm. Austria and Hungary are doing well aside from the unusual incidence of tuberculosis, and in Turkey a vigorous crusade has almost stamped out typhus.

News of the Week.

A Vaccine and Serum for Yellow Fever.—Mr. George Vincent, President of the Rockefeller Foundation, authorizes the announcement of the discovery by Dr. Hideyo Noguchi, at the Rockefeller Institute for Medical Research, of a vaccine for yellow fever which promises to confer immunity against the disease. The discovery of the yellow fever organism has also made it possible for Dr. Noguchi to develop a serum which it is believed will reduce the mortality from yellow fever. Already vaccination against yellow fever of people going to tropical countries is being made in New York. This work is being done at the Broad Street Hospital with vaccine furnished by the Rockefeller Institute. The first shipment of vaccine for yellow fever from the Rockefeller Institute to tropical countries was made a year ago when three hundred bottles were sent to Mexico. Other shipments have been made since then, the latest on Nov. 10. The Central American countries are so well convinced of the efficacy of Dr. Noguchi's vaccine that those who have been successfully vaccinated are permitted to travel without quarantine detention.

Smallpox Ravages Hayti.—A report from Rear Admiral Knapp, who is making a joint investigation of conditions in Hayti for the Navy and the State Department, shows that there are 788 known cases of smallpox on the island, 694 of which are in Port au Prince. The report adds that every effort is being made to get vaccine to the outlying districts. Aircraft, automobiles, trains, and pack mules are being used to get vaccine into the infected regions.

Typhus Suspects on an Atlantic Liner.—When the American Liner *Haverford,* from Liverpool via Queenstown, reached quarantine at Marcus Hook, Dec. 8, twelve steerage passengers were held as typhus suspects before the vessel was permitted to proceed to her pier in Philadelphia.

Pellagra and Income Vary Inversely.—After a three-year study of pellagra in the cotton-mill villages of South Carolina, the United States Public Health Service shows that pellagra varies inversely with the family income in this locality. As the income fell the disease was found to increase and to affect more and more members of the same family. As the income rose the disease decreased, and was rarely found in families that enjoyed the highest incomes, even though this highest was still quite low. It was found that expenditures for food, the intelligence of the housewife, the ownership of cows, gardens, etc., were also factors influencing the incidence of this disease. A recent statement by one of the large life insurance companies indicates that the food standards of Southern wage earners must have improved remarkably of late, for the death rate from pellagra has fallen from 6.7 per 100,000 in 1915 to 2.3 in 1919.

Public Health Service Issues Warning to Consumptives.—The migration of army patients suffering with tuberculosis to the semi-arid west is causing the United States Public Health Service no little concern, for all the Service hospitals and all the contract hospitals in that region are now completely filled. It is considered unfortunate that patients should leave places where the Government is ready and able to care for them and go to other sections where it is absolutely impossible for it to provide proper care and where even ordinary housing accommodations are largely unobtainable.

Anthrax Increasing in New York.—The *Monthly Bulletin* of the New York City Health Department for November presents the results of an investigation of 34 cases of anthrax occurring in this city from Jan. 1, 1919, to Oct. 1, 1920. A comparison of the number of cases during this period with previous five-year periods from 1900 to 1920 shows only 40 cases for three five-year periods from 1900 to 1914, inclusive, and 34 cases for the five-year period from 1915 to 1919 inclusive. One reason for this increase is the large quantity of hides that have passed through this city during the world war and the great demand for hair and bristles during the past five years. Of the 34 cases which the present report reviews, 23 recovered and 11 died. The fatal cases usually terminated before the eighth day. As 14 cases recovered without operation, and 9 recovered with operation, it seems logical to judge that it is best not to operate. Again, out of 14 that received only anti-anthrax serum, but two died. Out of 12 that received serum aided by other treatment, four died. The method which seems most successful, according to these observations, is the administration of anti-anthrax serum, 10 c.c. by local infiltration, every eight hours, and 40 c.c. intravenously, every four hours.

Rest and Health Home for Women.—The Women's Welfare Association of Washington, D. C., which established the Women's Evening Clinics seven years ago, has fitted up a house at Eleventh and L streets where working women can spend several weeks in a nursing ward and can have the benefit of medical examination and treatment. The home has a gymnasium and a physical training department, and the clinics are thoroughly equipped and conducted by the leading physicians of Washington. It is hoped to make this "Good Health Home" a model for the beginning of a nation-wide movement to establish such homes in every city and community.

New Hospital for Albany.—Mrs. James C. Farrell plans to build a million dollar hospital in Albany to take the place of the present St. Peter's Hospital. The new edifice will be erected on a large plot of ground in the Pine Hills section of the city and will be known as the James C. Farrell Memorial Hospital.

Law to Halt Making of High Heels.—The Massachusetts Osteopathic Society, at its annual convention in Boston, Dec. 4, announced that it would introduce a bill into the next Legislature placing a ban on the manufacture, sale, and wearing of high-heeled shoes. The proposed bill would limit the height of heels to one and one-half inches.

United States Public Health Service Corrects Misstatements.—Surgeon-General Cumming corrects the recently widely circulated statement that the United States Public Health Service had found that chaulmoogra oil was as efficacious in the treatment of tuberculosis as it had been shown to be in that of leprosy. He states that experiments made some years ago with the oil gave no results. Recent experiments with the ester, or derivatives, have been begun because of the hopes based on some

similarities between the bacilli of leprosy and those of tuberculosis; but these have not proceeded far enough to indicate what results will be obtained.

Dr. Rudolph Matas of New Orleans was elected Vice-President of the American Medical Association at a recent meeting of the Trustees of the Association, to fill the vacancy caused by the death of Dr. Isadore Dyer.

Surgeon J. W. Kerr of the United States Public Health Service sailed for Europe on Nov. 20 to assist in the investigation of immigrant conditions in Europe.

Professor Charles E.-A. Winslow of Yale University has been appointed to direct the public health work of the League of Red Cross Societies in Europe.

Dr. Edward J. Kempf, formerly clinical psychiatrist to the Government Hospital for the Insane, Washington, D. C., has opened an office at 100 Central Park South, New York City.

Charitable Bequests.—The will of the late Commodore Elias C. Benedict provides for legacies of $150,000 each for the Flower and Ophthalmic Hospitals, New York, and the Greenwich Hospital, Greenwich, Conn.

Phi Chi Medical Fraternity Convention.—The annual convention of the Alpha District of the Phi Chi Medical Fraternity will be held in Boston, Jan. 3 and 4, 1921, at the Fraternity headquarters of Delta Chapter, 144 Huntington Ave. The home of this Chapter is the medical school of Tufts College. The program will open with clinics by prominent clinicians at Massachusetts General Hospital, Boston City Hospital, Boston Dispensary, Carney Hospital, and the Salvation Army Hospital. A sight-seeing tour and visits to various medical schools and colleges of greater Boston will be conducted. Business sessions will be held each afternoon. A reception and smoker, followed by a banquet at the Hotel Vendome, will be given on the evening of Jan. 3.

The Automobile Death Rate During 1919.—According to figures recently given out by the Census Bureau at Washington, a total of 3,808 persons were killed in automobile accidents in the United States, or died as a result of injuries therefrom, during the last year. An automobile accident death rate of 14.1 out of every 100,000 of population was reported for 1919, an increase of 245 in the total number of deaths over 1918. In 1919 the rates for Kansas City, Mo., San Antonio, and Cleveland were much lower than for 1918, and give ground for the hope that with better regulation of traffic the rate in other cities may be lowered. Youngstown, Ohio, had the highest automobile death rate of any of the sixty-six cities on the list, namely, 28.5 per 100,000. New York had the largest total number of deaths, 780, an increase of 89 over the previous year, and a rate of 14.0 per 100,000. Chicago's total deaths numbered 328, with a death rate of 12.3.

The Radium Institute, located at 205 West Seventieth Street, New York City, has purchased five hundred milligrams of radium, which is to be used in equipping a new department of the institution.

Motor Cycles for Crippled Veterans.—A report from Melbourne, Australia, describes how, after many unsuccessful attempts had been made to solve the problem of locomotion for veterans who had lost both legs or one arm and one leg, the happy idea was conceived that a motor cycle sidecar might be altered so that it could be driven from the sidecar. This experiment has worked well and many generous citizens have donated motor cycles to the hospitals. The Red Cross Society has purchased twenty-five motor cycles and had them so altered as to be easily driven and controlled from the sidecar, thus enabling a number of crippled men to accept business positions.

Physician Arrested for Impersonating Health Officer.—A physician, practising in New York City, was recently arrested by an officer of the Sanitary Squad of the Department of Health, for impersonating an officer of the Department. He was released on bail and, in the Second District Magistrates' Court, was held for trial in Special Sessions. This physician had made a practice of visiting hotels and restaurants, representing himself as an officer of the Health Department, and demanding to see the food-handlers' certificates on file in these places. He then demanded that all those whose certificates were not on file be examined by him. The Sanitary Code provides that all food-handlers shall be examined, and shall not be permitted to continue work without a food-handler's certificate, but private physicians are not authorized to use this provision of the code to compel employers to have their employees examined. The Health Department permits private physicians to make these examinations, after written application has been made for such permission, and after authorization in writing has been sent to such physician.

The Brooklyn Cardiological Society.—The first meeting of the Brooklyn Cardiological Society was held at the office of the President, Dr. William J. Cruikshank, 102 Greene Avenue, Brooklyn, on the evening of Nov. 29, 1920. The following officers were elected: *President,* Dr. William J. Cruikshank; *Vice-President,* Dr. Glentworth Butler; *Secretary,* Dr. William W. Laing; *Treasurer,* Dr. Frank Bethel Cross. The following eminent cardiologists heve been elected to honorary membership in the new organization: Dr. Thomas Lewis, London, Eng.; Dr. Richard C. Cabot, Boston, Mass.; Sir James Mackenzie, London, Eng.; Dr. John Cowan, Glasgow, Scotland; Dr. Robert Hurtin Halsey, New York; Dr. William Thomas Richie, Edinburgh, Scotland, and Dr. William S. Thayer, Baltimore, Md.

The Union Health Center at 131 East Seventeenth Street, New York City, established by the International Ladies' Garment Workers' Union for the benefit of its members, to guard and promote the health of the workers in the garment industry, will be opened Saturday, Dec. 18, at 7.30 P. M. This is the first health center to be established on an industrial basis, and it is to serve the 100,000 workers of the International. Opening addresses will be made by Commissioner of Health Dr. Royal S. Copeland, Mr. Benjamin Schlesinger, President of the International Ladies' Garment Workers' Union, and other prominent persons.

More Soldiers' Hospitals Needed.—In his annual report sent to Congress on Dec. 11, Dr. Hugh S. Cumming, Surgeon General of the Public Health Service, asked for additional hospital facilities for the treatment of former service men and women,

and the appointment of an administrative head for the three agencies involved in rehabilitation work. Dr. Cumming points out that 20,000 patients were receiving hospital care from the Public Health Service last July 1, as compared with 2,000 in October, 1919, and urges Congress to make available funds for new construction. Under Dr. Cumming's plan the War Risk Insurance Bureau, the Federal Board for Vocational Education, and the Public Health Service should operate under an administrative head as coordinate and independent bureaus in close cooperation.

Health Department Makes Crusade Against Poor Food.—The work of the Bureau of Food and Drugs of the New York City Health Department shows that the adulteration and selling of food unfit for human consumption has assumed menacing proportions. The Department has 300 of these cases before the courts at the present time, and since the beginning of the year has collected $35,000 in fines for violations of the sanitary code affecting the adulteration, storage and sale of food products. Since Jan. 1, 1919, the Department of Health has condemned 17,256,004 pounds of foodstuffs. In order to put a check on these violations of the sanitary code thirty women of the sanitary reserves have been sent out to inspect the restaurants and food stores of the city.

Police Oppose Hospital Plans.—The rank and file of New York's police do not want the $5,000,000 police hospital that is being fostered by Police Commissioner Enright and the deputy commissioners. The Patrolmen's Benevolent Association have held a meeting at which they voiced their objections to such an institution. They state that there is not sufficient demand on the part of patrolmen to warrant the expenditure of such a large sum of money, and say that when ill they prefer to be taken to a hospital of their own selection near their homes. They do not wish to be regarded as a special class looking for or in need of charity. They prefer a salary in keeping with the work they perform and the risks they undergo out of which they may pay for proper treatment when sick.

Medical Society Elections.—THE NEW YORK SOCIETY OF MEDICAL JURISPRUDENCE, at its 313th regular meeting held Dec. 13, 1920, re-elected the officers which have served during the past year. These are as follows: *President,* Dr. Nathan B. Van Etten; *Vice-President,* Charles Oakes, Esq.; *Treasurer,* Charles P. Blaney, Esq.; *Corresponding Secretary,* Dr. Edward E. Hicks; *Recording Secretary,* Dr. L. Howard Moss.

Vacancy in Bureau of War Risk Insurance.—The United States Civil Service Commission announces an open competitive examination for Chief, Section of Medical Referees, at a salary from $4000 to $6000 a year. Vacancies in positions requiring similar qualifications, at these or lower salaries, will be filled from this examination. The examination is open to both men and women. The duties of the appointee will consist of supervision of the Section of Medical Referees engaged in examining case files and making disability ratings based upon the medical evidence contained in reports of physical examinations obtained from medical officers in the field and other routine work connected with the medical aspect of claimants. Applicants must have been graduated from a medical school of recognized standing, and have had at least five years' active practice, at least one year of which must have been spent in a modern well-equipped hospital. The receipt of applications closes Jan. 11, 1911. Applicants should apply for Form 1312, stating the title of the examination required to the Civil Service Commission, Washington, D. C.

Openings for Dietitians.—The United States Public Health Service announces that opportunities are now open in the hospitals of the Public Health Service for the employment as dietitians of many women graduates of schools of household economics who have had student training or hospital experience in civilian or army hospitals. Applications for appointment should be made to the Surgeon General, United States Public Health Service, Washington, D. C.

Obituary Notes.—Dr. RICHARD A. PYLES, a graduate of Washington University, in 1883, died after a long illness at his home in Washington, D. C., on Dec. 5, at the age of fifty-eight years. For many years he was surgeon in the District of Columbia National Guard and was major and surgeon in chief of the First District United States Volunteer Regiment in the Spanish war.

Dr. WILLIAM J. BURNETT, a graduate of the University of Michigan Medical School, in 1869, died at his home in Woodmere, L. I., on Dec. 6, at the age of seventy-seven. Dr. Burnett formerly practised medicine in Long Island City, and later became President of the Long Island City Savings Bank.

Correspondence.

INCONCLUSIVE EXPERIMENTS REGARDING DRUG ADDICTION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I have been greatly interested in an article appearing in the *Archives of Internal Medicine* of Sept. 15, 1920, by Pellini and Greenfield dealing with animal experimentation of an exceedingly technical nature. The authors have arrived at certain conclusions, which conclusions have been accepted by certain organs of the lay and semi-scientific press as ultimate and authoritative, and interpreted in certain of them to mean that opiate addiction has no physical basis but is simply a social vice or habit of indulgence.

The importance from a scientific point of view of accurate observation and critical analysis of deductions drawn from observed phenomena is axiomatic, and what is true from a scientific viewpoint *per se* is doubly true from a public health administrative viewpoint, epecially when dealing with a subject of such vital importance as that of narcotic drug addiction. Otherwise legislators, administrators, and the public may not be safeguarded against the possibility of hasty interpretation, misleading conclusion, and hence dangerous application.

In view of the immense amount of recorded data at variance with the conclusions of the authors, and the extreme caution manifested by most scientific men in interpreting any phenomenon observed in experimentation of an immunological nature, I feel that we should be extremely cautious in drawing conclusions from this single piece of work.

For the past nine or ten years I have been deeply interested in the subject of narcotic drug addiction, first taking this problem up as a public health activity while Health Officer of Jacksonville, Florida. Since then I have made more than one extensive review of the related literature and have followed very closely current work both clinical and experimental, and as one seeking information upon every angle of this important subject, I would much appreciate from you or your readers any data or discussion that may throw light upon this and the many other problems of the unsettled narcotic drug situation.

C. E. TERRY, M.D.,

Chairman, Committee on Habit-Forming Drugs, Food and Drug Section, American Public Health Association.

DARIEN, CONN.

RESPONSIBILITY OF THE STATE FOR DRUG ADDICTS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It is a well-known fact that poor suffering drug addicts, in their intense desire to obtain drugs to the use of which they have become enslaved, will sacrifice anything, regardless of truth or loyalty, to further if possible the chance of an immediate and perhaps future supply of the narcotics they are hungering for, even though as a matter of fact their hopes for such supply are groundless. This serves to illustrate their entire irresponsibility as witnesses or as trustworthy citizens.

Therefore I maintain that any State which refuses or neglects to provide an institution or other means for the humane care and treatment of these unfortunates should be held accountable as an accessory to whatever misdemeanor or crime a drug addict may commit.

J. C. BATESON, M.D.

SCRANTON, PA.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Nov. 20, 1920.

First Meeting of the London Association of Medical Women's Federation.—The first meeting of the above association was held on Nov. 9 last, Mrs. Fleming, M.D., being in the chair. Dr. Helen Chambers read a very interesting paper on cancer research in radiotherapy. She said in part that the treatment of malignant disease by irradiation could be considered from two aspects: (1) The physical conditions necessary to ensure that the cancer cell absorbs a dose of radiation sufficient to cause its death, and (2) the effect of irradiation treatment upon the general state of resistance of the patient to the growth of undamaged cancer cells. The first of these necessitated a detailed knowledge of the physical nature of the type of radiation used and the absorptive power of the tissues at different levels. It also called for a knowledge of the dose of radiation required to kill the cancer cell. This dose, the rad, had been determined for certain tumors by Professor Russ, and for others by Prince and Wood working under the Crocker Fund in New York. The second consideration, that of the production of immunity to malignant diseases, had been the aim of all research workers on cancer in the past. Largely as the result of work by Haaland it had been the general opinion that immunity to transplanted cancer in animals could be produced only by the absorption of living tissue, particularly by living cancer tissue. This outlook precluded the production of immunity as a practical problem of treatment. It had not yet been shown that immunity could be produced in spontaneous tumor-bearing animals. Dr. Chambers thought that there was no reason to believe that the reaction of human patients would differ materially from the reaction of animals to malignant disease. It had been shown by Contamin and later by Wedd, Morson and Russ, that the absorption of irradiated tumor tissue produced active immunity in animals. In that case the irradiated tissue which caused immunity gave no evidence of life after inoculation. On the other hand, if the irradiation had not been sufficient to prevent growth no protection was obtained. The antigen causing immunity could be regarded as a product of the damaged tumor cell, for actively growing carcinoma caused no protection; there was indeed some evidence that it caused increased susceptibility. All attempts to separate the antigen from irradiated carcinoma material had so far entirely failed; it was a body, or group of bodies, which is easily destroyed, and the conditions under which it exists are not yet known. The evidence indicated that it was desirable to treat cases of malignant disease first by irradiation of the primary tumor, whenever possible with a lethal dose to the tumor cells, and to follow this treatment by surgical operation.

The Venereal Problem.—The *Lancet* of this date refers to an article on venereal disease which appeared in the September number of the *International Journal of Public Health* from the pen of Mr. Walter Clarke, assistant editor of that journal and acting chief of the Department of Social Hygiene of the League of Red Cross Societies. Certain conclusions arise out of a careful perusal of Mr. Clarke's paper: (1) That although the bulk of legislation in the newer Anglo-Saxon communities, and notably Canada, South Africa, Australia, New Zealand, and the United States, is too recent to allow of passing a final judgment as to success, yet on the whole the working of compulsory notification is regarded as satisfactory; (2) the problem of prostitution has received elsewhere much more serious attention as a factor contributory to venereal disease than it has in Great Britain; but although there is need for the investigation of professional prostitution in Great Britain, difficulty is presented by the increasing prevalence of promiscuous intercourse in all classes of society. This phase of the problem may tax the diagnostic acumen of the most searching investigators; (3) the American Federation of Labor, assembled in convention, indorsed the efforts of the United States Public Health Service, co-operating with the various States, in combating the spread of venereal diseases, and called upon organized labor to assist in every possible way the eradication of these scourges of civilization. The writer in the *Lancet* expresses the hope that the labor party in this country will not do less towards the solution of a problem which involves

the life and happiness of all classes of the community.

The Tuberculosis Bill.—Owing to the opposition evinced towards bills recently brought before the House of Commons by the Ministry of Health, these bills have been deleted as to the obnoxious features or very considerably pared down. One of the last of the Ministry of Health bills to be "cut" was the Tuberculosis Bill. This is the bill which imposes upon county and county borough councils the duty of making provision for the treatment of tuberculosis in sanatoriums or other approved institutions. The bill also empowers these councils to provide and maintain village settlements for the benefit of persons suffering from tuberculosis, and their families. The village settlements and other proposals of a minor character are now to be dropped. The bill will as a result of this decision simply provide for the transfer of the duties of the insurance committees under the National Health Insurance Act, so far as they relate to the treatment of tuberculosis to these councils. The transfer was sanctioned by Parliament when the bill amending the insurance act was passed last year, and in its limited form the present measure is not likely to meet with much criticism from those who are resisting proposals entailing increased expenditure falling on either the rates or taxes.

Rates and Public Health.—A good deal of criticism has been leveled recently against the Ministry of Health, both in Parliament and outside, for the manner in which they are increasing the burdens on the ratepayers and proposing to further increase these burdens by far reaching schemes to ameliorate the health of the people. In his defense of the Ministry, of which he is the head, Dr. Addison the other day in an interview said that it was the fashion at the moment to attribute the large rate increases to the Ministry of Health. But the facts were these: By the assistance of the officers in eighteen typical boroughs in different parts of the country, there had been obtained recently an analysis of the causes of the increase in rates, and a return on this subject had been made to Parliament. The average increase in the rates in the pound during 1920-21 over those of 1918-19 was ten shillings and seven pence gross, or more than 100 per cent. Producing a table showing the items of increased expenditure attributable to the new services required by the Ministry of Health, and forming part of what is described as "new work" by the local authorities, Dr. Addison said it would be seen that increases of wages and salaries, with the added cost of materials and contracts, amounted to nine shillings and six pence half-penny out of the ten shillings and seven pence, while the whole of the "new work" was only responsible for four pence and three farthings. Dr. Addison pointed out that the new work included the construction of new roads, housing, extensions of hospitals and sanatoriums, the treatment of venereal disease, maternity and child welfare, and other items. Nearly all the increased expenditure arose from the fact that local authorities had found themselves obliged with all others, to pay a great deal more for everything they buy, and to make increases in wages and salaries to meet the increased cost of living. As to how far expenditure on health matters was justified the Minister observed that health was not always capable of monetary valuation, and often not of statistical computation in any form. However, there was one form of expenditure the value of which could be computed. The infant mortality rate was one of the most valuable and sensitive indices of the health of a community. The distressing revelations of the after effects of ill-nourished childhood in the C-3 class which formed the subject of much anxious comment during the war must not be forgotten. The promises of the future in this direction seemed to be even brighter than the achievements of the past. For if the returns for 1920 were taken the remarkable fact would be found that the infant mortality rate in each of the three completed quarters of the present year was the lowest on record. In 1911 the infant mortality rate for England and Wales in the second quarter was over 200 per thousand. The last quarter it had fallen to 65. The striking improvement during the past year was, of course, due to more than one cause, but it was certainly fair to say that it was in the main due to improved maternal nutrition and care, and to the improved quality and extent of the services of personnel, attention, and instruction, which had been afforded by the local authorities in their infant and child welfare schemes, with the active assistance of many patriotic outside bodies.

Dental Clinics for Adults.—Pending the adoption of a national dental scheme Sir Philip Sassoon, M. P., had inaugurated at Folkestone a dental clinic for adults which it is thought will demonstrate the possibility of securing the maximum of skilled dental treatment at the minimum of cost to all concerned. Under arrangement with the Folkestone Town Council, the clinic is situated in the same rooms as those used for the school clinic. Strict precautions will be taken so that the facilities offered by the clinic are not abused. On the other hand, in cases of real necessity, no man or woman needing treatment will be turned away because he or she is unable to pay.

Murder of a British Member of the Indian Medical Service.—Colonel Foulkes, I. M. C., was shot dead recently in his bungalow by a number of tribesmen, and his wife was seriously wounded.

LETTER FROM BELGIUM.

(From Our Own Correspondent.)

LIÈGE, November 6, 1920.

International Congress of Military Medicine and Pharmacy.—The Belgian Army Medical Staff has organized an international Congress of Military Medicine and Pharmacy to be held in Brussels in June, 1921. To it will be invited all physicians and pharmacists who served in the army of the allied and neutral nations. At the end of the great events which disturbed the nations of the world from 1914 to 1918, it will be interesting to review the work of the different sanitary services and to compare the various teachings, with the view to mutual benefit, and it will also be useful to make a permanent record of the advances in medicine made during the war, in order to render them of use in the future.

The following questions will be discussed: (1) The lessons of the war regarding the treatment of fractures of the extremities. (2) The antivenereal and antituberculous campaigns of the army. (3) The chemical and physiological study of the gases used in warfare, including the results of their action on the organism and the importance of the knowledge of these results in determining invaliditiy pensions. (4) The general organization of the Sanitary Service in the armies.

Subscriptions to the Congress, as well as communications and reports on the different questions above mentioned, should be sent not later than April 1, 1921, to the Secretary General of the Congress, Dr. Jules Voncken, Hôpital Militaire, Liège, Belgium. Each paper should be accompanied by a brief summary.

Cattle Plague.—The epidemic of cattle plague seems to be definitely at an end. The two or three centers of the disease which still exist in the northwest of the country are very evidently being extirpated. It was through prophylactic and collective hygienic measures that this plague has been overcome in spite of its terrible gravity. We may draw from this incident valuable knowledge for the prophylaxis of transmissible diseases in general. The success of a struggle against these epidemics rests upon the preventive measures instituted by an intelligent, instructed cooperation. Efforts in the line of preventive vaccination are perhaps destined to meet with greater difficulties, greater obstacles than are well-considered and energetic hygienic measures. The lesson of the cattle plague in Belgium is a striking example of this.

The Present Treatment of Joint Lesions.—Under this title, Prof. Willems has published in three successive numbers of *Liège Médical* (Organ of the Faculty of Medicine of Liège) a very detailed study of the treatment of joint lesions by immediate, active mobilization. He passed in review one by one, simple wounds of the soft parts of the joint and wounds with bony involvement, these two varieties of wounds being treated under two heads, whether they are sterile or infected. As might have been expected, this is a very clear and categorical review of a method of treatment of joint troubles which has already rendered great service. It should, however, be still further insisted upon. As Georges Gross has said in the notable treatise on Reparative and Orthopedic Surgery by Jeaubran, Ombrédanne, and Nové-Josserand, this method is undoubtedly the method of the future.

Treatment of Peritoneal Exudations by Ether.—In an interesting communication made to the Royal Medical Society of Gand, Dr. Colson reported favorable results obtained by the local use of ether in the abdominal cavity in cases of peritoneal infection. Of five cases operated upon in extremis, three recovered. The method consists of subumbilical median laparotomy and evacuation of the pus found in the abdominal cavity; then a second incision is made in the region of the appendix and finally a half liter of ether is poured into the abdomen. Two drains of moderate size are then inserted into the dependent portion of the abdomen and the patient is placed in Fowler's position. The fluid collects in the pelvis where absorption is at a minimum and pressure is greatest, owing to the weight of the intestinal coils. The postoperative treatment is the same as that ordinarily employed after abdominal section. The ether acts not only as a germicide but also as a heart tonic.

Treatment of Trachoma by Arsenobenzol.—Dr. Henri DeWaele has recently proposed the treatment of trachoma by means of arsenobenzol, this method being based upon the assumption that trachoma is due to the presence of a protozoon parasite. He reported to the Royal Academy of Medicine of Belgium some cases thus treated by means of an ointment of 1 per cent. of salvarsan.

1. Leucocytic Reaction in a Paratyphoid Dysentery and Following Vaccine Inoculations. Geneva Tryon.
2. The Combined Operative and Radium Treatment of Malignant Disease of the Nasal Accessory Sinuses. Harry A. Barnes.

1. The Leucocytic Reaction in a Paratyphoid Dysentery and Following Vaccine Inoculations.—Geneva Tryon, during an epidemic of dysentery in 1915 in the Boston State Hospital, conducted this investigation. The organism which caused the disease belonged to the paratyphoid enteritidis group, but could not be identified with any of the well known members. Clinically, the disease appeared in three forms: a dysenteric-pneumonic, a dysenteric, and a diarrheal. The duration of the disease was from five days to three weeks. The majority of the cases occurred among the old and feeble women patients in the Infirmary Department. Because of some isolated observations of a polymorphonuclear leucocytosis, it seemed worth while to study the leucocytic reaction more carefully, and during the seventeen months following the first outbreak of the disease several series of examinations were made. The leucocytic reaction consisted of a hyperleucocytosis, with the highest count rising but little above twice that of the normal count for the individual and a relative increase in polymorphonuclears at one or more periods during the following twenty-four hours, this relative increase not always being synchronous with the highest total count. The individuals chosen as normal cases in the series of examinations had no record of having had an attack of dysentery or diarrhea. In comparing the leucocytic reaction with the clinical history it was concluded: (1) That the stronger normal individuals show more reaction to subcutaneous injections of vaccine than the weaker ones who have had the disease and recurrent attacks. (2) That the leucocytic reaction for the individual is more marked during or immediately after an attack of the disease and diminishes with recurrent attacks, which corresponds to the clinical observation that the resistance of the individual to the disease is lessened by a previous attack. (3) The fact that there may be a polymorphonuclear reaction to a subcutaneous injection of vaccine, coincident with the cessation of a diarrhea would indicate the use of a vaccine therapy. In the few cases in which this treatment has been given the results have been favorable for a recovery from an attack. Detailed tabulations of the leucocytic reactions are given.

5. Epilepsy Treated with Luminal.—Harvey M. Watkins reports some brief observations with luminal covering a period of three months during which time the drug was administered to 22 patients, no other medicine being used except an occasional laxative. Seven of the patients were of the idiopathic type, five were patients in whom the petit mal seizures predominated, two were status patients and the remaining eight were those in whom there was an equal distribution of grand mal and petit mal seizures. The method of administration was one and a half grains in tablet form twice daily, night and morning. It was found that luminal reduced the total number of convulsions in all classes sixty per cent., although a small proportion of patients had an increased number of convulsions during its use. It had practically no effect upon some patients, and about ten per cent. showed untoward symptoms from its use. It had all the bad effects of bromides with the exception of the rash. Cures are not to be expected as luminal is at best a palliative remedy; it is not virtually a specific. It must be used over a long period of time and continually, as once its administration is discontinued the epileptic habit returns with increased severity. Undoubtedly luminal serves a field in the therapeutics of epilepsy. It is worth a trial in every case but to determine its relative value it will be necessary to use it in a great number of cases and over a long period of time.

8. Injections of Cerebrospinal Fluid in Cerebrospinal Fever.—Navroji A. Cooper reports the case of a boy fourteen years old suffering from a severe form of cerebrospinal fever, with complete recovery from the malady as well as all its concomitant adverse symptoms, nervous, sensory, and muscular, under the injections of the patient's own cerebrospinal fluid. The case was very serious and of a severe form of cerebrospinal meningitis from the very beginning. The disease in its initial stage simulated rheumatism, but neither the salicylates nor other medication had any effect on its course. If anything, the condition went from bad to worse, a bronchopneumonia supervening. There was a distinctly good effect from the mixed influenza vaccine in the bronchopneumonic condition, but not on meningeal symptoms. After the administration of the vaccine and urotropin the cerebrospinal fluid was found sterile and clear. It is certain that both the vaccine and urotropin had no effect on his meningeal symptoms and fever. But the fever and meningeal symptoms abated gradually every day under injection of the cerebrospinal fluid. The patient's complete recovery was due to the injections of his own toxins contained in the cerebrospinal fluid without which, the author believes, the patient could not have made an advance toward such an uninterrupted and perfect recovery.

11. Diagnosis and Treatment of Amebic Abscess of the Liver. Tom S. Mebane.

2. The Roentgenologic Diagnosis of Gallbladder Lesions.—Dudley Roberts has secured his most satisfactory results with a fine focus gas or hydrogen tube, a plate target distance of from 28 to 30 inches, a small diaphragm and long cone giving an exposure field of only 5 or 6 inches. A parallel spark gap of 2½ to 3½ inches is regularly used, and a milliamperage of from 20 to 30 in the tube. Exposures are made with the patient prone on the cassette during forced, sustained expiration. The effort is made to under expose the film slightly and push the development short of causing fog or stain in the effort to bring out detail. Statistical studies of diagnostic results are extremely unsatisfactory, as chance enters so largely, particularly if the series of cases is small. From his experience the writer draws the following conclusions: (1) The roentgenologic diagnosis of gallstones and the dilated gallbladder with a small percentage of failures is possible at the present time; (2) negative diagnosis has a value that is proportionate to the intensity of detail and sharpness of image secured in the given case. Negative diagnosis has very little value in subjects so heavy that satisfactory roentgenograms cannot be made. Subjects of slight or medium body thickness can be roentgenographed with an intensity of detail that justifies an experienced interpreter in a negative diagnosis of stones or a dilated gallbladder; (3) the roentgenologic diagnosis of gallstones necessitates such an expenditure of time and money in the taking of satisfactory exposures, and so much experience in the interpretation of intensely detailed roentgenograms, that it is not at present a safe and practical method of diagnosis for general adoption. Ten or fifteen per cent. of stones can be plainly visualized even by an extremely poor equipment and technique, but under such conditions the importance to be attached to negative findings is negligible; (4) gallbladder roentgenograms of satisfactory detail can be made only with direct rays of low penetrating power, and duplitized films with fast screens; (5) an insuperable limitation of roentgenologic diagnosis of gallbladder lesions is the apparent impossibility of securing roentgenographic evidence of chronic cholecystitis without dilatation or of new growth of the gallbladder and biliary ducts.

3. Nontuberculous Lung Changes Following Pneumonia.—Edward N. Packard holds that on account of the recent high incidence of pneumonia, a great many chronic lung changes will be encountered in the next few years. The signs and symptoms of the compensatory and degenerative changes following unresolved pneumonia often mislead in diagnosis. The apical findings in an emphysematous chest often mislead—sometimes simulating a tuberculous lesion, sometimes masking a real tuberculosis. With the overgrowth of fibrous tissue in the lung there is also bronchial dilatation and frequently infection (chronic bronchitis, bronchiectasis). These changes, unlike tuberculosis, are almost always basal. Packard agrees with Lawrason Brown in the belief that abnormal physical signs at one apex should be considered as due to pulmonary tuberculosis, until proved not to be; while those at the base should be looked upon as not tuberculous until definitely proved so.

5. A Critical Review of Five Hundred Cases of Gastric and Duodenal Ulcer.—Elmer L. Eggleston excludes from the five hundred cases reviewed cases which occurred prior to 1912, being convinced that before this time the study of ulcer was not made in conjunction with the roentgenologist, and that the possibility of error in diagnosis was so great as to rob the statistics of much of their value. Of the 500 cases, 415 were classed as duodenal and 85 as gastric. From this review the writer concludes: (1) If peptic ulcer, particularly duodenal ulcer, is observed early in its history, and if the patient will submit to a carefully planned course of treatment for a reasonable time and will follow up this treatment by a carefully regulated dietary regimen over a period of some months, one can be sanguine of obtaining complete cure. (2) In uncomplicated cases of long standing, proper medical treatment provides relief in at least 70 per cent. of the cases. (3) In the great majority of cases in which the symptoms disappear during a course of medical treatment and there is later a return of the symptoms, the fault is due to dietetic carelessness. (4) Surgical treatment is to be preferred for the cases complicated by pyloric stenosis not yielding readily to medical measures, cases showing repeated hemorrhage, penetrating or perforating ulcers, and for cases in which a prolonged medical course is impossible. (5) Simple gastroenterostomy fails to provide permanent relief in a con-

siderable number of cases, and should be supplemented by resection of the ulcer, cauterization, infolding or partial gastrectomy.

5. Further Experiments for Preservation of Lemon Juice. P. W. Bassett-Smith.

2. Pregnancy and Latent Syphilis.—R. A. Hendry, discussing the interrelationship between pregnancy and syphilis, reached the following conclusions: (1) That the clinical evidence of syphilis is unreliable; (2) that the Wassermann reaction is the test by which, at present, the diagnosis must usually be made; it must be borne in mind that a "negative" or a "slightly positive" reaction may accompany syphilis during pregnancy, and, moreover, that a "positive" may occur in a nonsyphilitic individual; (3) that the examination of stillbirths furnishes reliable, but, at present, insufficiently available, evidence; (4) that the institution of mercurial treatment before the pregnancy justifies a favorable fetal prognosis; (5) that the prognosis when treatment is begun during the pregnancy depends on the unknown and already present degree of infection of the fetus.

Amand Routh, discussing spirillolysis and its causation, recalls the fact that when the *Spirochæta pallida* was discovered it was found to be larger than the spermatozoon's head, and was a large infecting agent relative to the mature ovum. If an ovum was able to be infected at the moment of fertilization via the parental semen, or by spirochætes in the mother's tissues previous or subsequent to fertilization, it was impossible to understand why such a large infecting organism, capable of unlimited multiplication, did not invariably destroy the delicate embryo, or to explain how such infected fetuses ever survived their birth—to explain, in fact, how the infection of syphilis tended to become latent during pregnancy. It is known now, he points out, that the spiral nature of the mature spirochæte is able, under the action of various substances, or even by a spontaneous spirillolysis, to break up into "granules," generally by a transverse division. The many interesting facts brought out in this connection by Noguchi and others make it probable that the spirochæte may become granulosed during pregnancy, and it also makes it possible that in some cases infection may be by means of the granules and not by the mature organism. The further problem is to determine the agents which nature has provided for this spirillolytic action on the *Spirochæta pallida* during pregnancy.

It is evident that it must be some agent which is present very early in pregnancy, in order to prevent almost immediate destruction of the fertilized ovum infected by the *Spirochæta pallida*. Such agency must also continue in action during the pregnancy, or there would be no chance of a child being born alive or of surviving in utero long enough to be treated through its mother. The writer had proposed, as early as 1914, that the chorionic ferments or "syncytial toxins," or their derivatives, have this granulosing power. These ferments of the chorionic villi are intended for trophoblastic purposes to facilitate the burrowing of the fertilized ovum into the uterine mucosa at the placental site. Any excess of the syncytio-toxins is apparently controlled or neutralized by so-called syncytio-lysins, as a result of the trophoblastic action on the maternal tissues. Failure of such control may be the cause of the various serious autoxemias of pregnancy. If the chorionic ferments are able to exert a destructive or digestive action on the local, probably prepared maternal tissues, it would probably be able to act chemically on the spirochæte, and make it break up into granules. The resulting granules, in Routh's opinion, are kept biologically inactive by the ferments and remain "latent," so that they do not "sprout" or multiply in the tissues of the maternal or fetal portions of the placenta so long as the chorionic ferments are present and no mature spirochætes are able in an ideal case to pass from mother to child, or vice versa, and the infection would remain latent during the pregnancy. After pregnancy, Routh says, the chorionic ferments gradually disappear from both the maternal and the fetal tissues, so that the biological activity of the granules may then be resumed and the mature organism may become developed.

John Adams, giving the results of three years' treatment of syphilitic mothers and babies, summarizes by saying that a pregnant woman with syphilis, whether active or latent, if treated for three or four months before her confinement, will probably be delivered of a healthy child at full term.

4. Treatment of Diphtheria Carriers with Detoxicated Klebs-Loeffler Vaccine.—A. Reith Fraser reports three cases showing the results obtained. He holds that the length of time during which these cases were carriers of virulent bacilli is important. Since vaccines when given in sufficient doses can have such a marked effect on the virulence of the organism or on the organism itself in such difficult cases they will certainly cure convalescents where resolution is delayed. It is generally conceded that the convalescent with an otherwise unhealthy nasopharynx is most prone to become a chronic carrier. Here is a point in common in the three cases reported: In the first a nasal polypus, in the second congenital syphilis, and in the third a gunshot wound. The first had an attack of diphtheria, while the other two had not. In spite of these ideal conditions for bacterial growth, disappearance of the virulent diphtheria bacilli followed detoxicated vaccine treatment. Other organisms with the same morphology, but nonpathogenic, could still flourish on the site, as a mixed vaccine was not used. Exactly what determines the chronicity of carriers is not yet by any means clear. We are still unaware of the mechanism whereby the convalescent with delayed resolution becomes free. In spite of a multitude of varied efforts, no certain means of clearing up chronic carriers has yet been evolved. The cure of carriers is the most hopeful form of prophylaxis. One would expect the vaccine to confer more or less protection on those exposed to infection. Here one has, then, a method of promising efficiency in dealing with contacts, convalescents, and carriers. Antitoxin protects only from the toxin produced by the living Klebs-Loeffler bacilli in the tissues. The vaccine prevents the growth and life of the bacilli. In a case of diphtheria both vaccines and antitoxin should be given. The advantages of dosage allowed by employing detoxicated vaccine must not be overlooked.

Thornwaldt's Disease.—Baillet gives a brief account of this affection. The discoverer, a practitioner of Dantzig, first reported the new malady in 1887. The latter was a suppuration which apparently was seated in Luschka's canal in the pharynx. The said canal was first mentioned by Mayer in 1842, Luschka's account, which was much more detailed, having been published in 1868. In the same year von Troeltsch described a cyst of this cavity. Thornwaldt's contribution came next in order. The so-called "pocket" is in reality a cul-de-sac, a canal which measures about 1½ cm. in depth, which is very difficult to disinfect—hence the tendency to chronic recurrent suppuration. Naturally the condition shades into inflammation of the pharyngeal tonsil and to suppuration in the ethmoidal and sphenoidal cinuses, so that diagnosis during life is very difficult. The question is largely an academic one, as the treatment involves curetting the nasopharynx. If the condition persist the pathologically altered canal of Luschka should in theory be extirpated, but this is said by Ballenger of Chicago to be impracticable in a part of the cases. It may be undertaken in two stages. By means of curved scissors the adenoid tissue is first excised; one blade is then inserted into the canal and used as a curette to destroy the pyogenic membrane. The author believes that a very small curette should answer as well.

Book Reviews.

AN ATLAS OF THE PRIMARY AND CUTANEOUS LESIONS OF ACQUIRED SYPHILIS IN THE MALE. By CHARLES F. WHITE, O.B.E., M.B., Lecturer on Venereal Diseases, Rochester Row Military Hospital, and W. HERBERT BROWN, M.D., Physician for Diseases of the Skin, Victoria Infirmary, Glasgow. New York: William Wood & Company, 1920.

THIS atlas comprises 79 ordinary photographic representations of disease with four colored plates. The six chapters are devoted respectively to primary syphilis, extragenital chancres, non-syphilitic or soft sores, secondary or cutaneous syphilides, late or tertiary syphilides and common skin-diseases frequently mistaken for syphilis. Since the highest function of an atlas must be to teach differential diagnosis, the present volume can be specially recommended to the general practitioner.

MEDICAL RECORD VISITING LIST OR PHYSICIAN'S DIARY FOR 1921. Revised. New York: William Wood and Company.

THIS well-known visiting list appears in good time; it contains the customary blank pages for names of patients with date of attendance, and special blanks for consultation practice, obstetric engagements and practice, vaccinations, register of deaths, addresses of patients and of nurses, and cash account. At the beginning of the volume there will be found the usual miscellaneous information, such as tables of dosage and of date of labor, treatment in emergencies, etc. The arrangement of the volume is all that can be desired; its size and appearance are also attractive.

THE TOPOGRAPHICAL ANATOMY OF THE LIMBS OF THE HORSE. By O. CHARNOCK BRADLEY, M.D., D.Sc., M.R.C.V.S., Principal of the Royal Veterinary College, Edinburgh. New York: William Wood & Company, 1920.

THIS little volume comprises 172 pages and 115 illustrations. The latter include no radiograms but are very elaborate and exhaustive and prepared from original dissections. The seven chapters comprise as subjects the thoracic limb, hoof and contents, arteries of thoracic limb, nerves and blood supply to the muscles of the same, the pelvic limb, arteries of pelvic limb, nerve and blood supply of the muscles of the same. The blood vessels and the muscular insertions on the bones are shown in colors.

THE THEORY AND PRACTICE OF MASSAGE. By BEATRICE M. GOODALL-COPESTAKE, Examiner to the Incorporated Society of Trained Masseuses, etc. 2nd Edition. New York: Paul B. Hoeber, 1919.

THIS book has 265 pages and 67 illustrations. The number of chapters is 23, arranged in three sections devoted respectively to general principles of massage, massage in surgical conditions and in medical conditions. Aside from neuro-muscular affections, fractures, and dislocations, massage is indicated in affections of the abdominal viscera, in arthropathies including acute rheumatism, in circulatory stasis and in pregnancy. A chapter is devoted to the after-treatment of war injuries.

PHYSICAL RECONSTRUCTION AND ORTHOPEDICS. By HARRY EATON STEWART, M.D., Captain Medical Corps, U. S. Army, Division of Orthopedics; Assistant Director, Section of Physiotherapy, Surgeon-General's Office; Instructor in Medical and Orthopedic Gymnastics and Massage, New Haven Normal School of Gymnastics; Attending Surgeon, New Haven Orthopedic Dispensary; Formerly Instructor in Corrective Gymnastics, Teachers' College, Columbia University. Authorized for publication by the Surgeon-General of the U. S. Army. 67 original illustrations and two diagrams. New York: Paul B. Hoeber, 1920.

RECONSTRUCTION has become the watchword of the hour, and this volume is one of the forerunners of what will become, we predict, a valuable literature. The author has devoted the first third of the book to physical reconstruction, and the other two-thirds to orthopedics. His remarks on the use and abuse of exercise are good. Massage is fully dealt with. Vocational therapy is only lightly touched and in his suggested prescription blank for its subjects he uses the term "functional neurosis," which is tautological, and "insanity," which is undesirable. His discussion of orthopedic conditions consists of a brief description in each case followed by an account of the exercise recommended. The chapter on foot strain is especially valuable, dealing with flat foot, bunions, corns, etc. Many pictures illuminate the text, and the work as a whole will be found of great value in dealing with a class of patients who deserve our utmost attention.

UNTERSUCHUNGEN ÜBER DIE MYELOMKRANKHEIT. Von ARVID WALLGREN. Upsala: Almquist & Wiksell, 1920.

THIS Swedish work appears also or perhaps solely in German text and is based on studies made in the University Medical Clinic and Pathological Institute. The chapters are devoted to etiology clinical symptomatology, blood changes, Bence Jones's albumins, general and visceral symptoms, autopsy finds, histology, the myeloma cell, alternative of local tumor or systemic disease, clinical diagnosis, prognosis and treatment, and case histories. The latter number 14, and but one patient still survives. There are 17 microphotographs. The monograph is a most thorough one.

BACKWATERS OF LETHE. Some Anesthetic Notions. By G. A. H. BARTON, M.B. London: H. K. Lewis & Co., Ltd., 1920.

FOUR essays in this small volume are devoted respectively to chloroform, alkaloidal anesthesia, gas anesthesia, and modern methods. The essay entitled *arma virumque cano* deals with apparatus; that on "the haven" is devoted to the anesthetic sequences used by the author, together with his special apparatus, while "schools and rapids" deals with the disturbances of anesthesia. The title of the book and of several of the essays are illustrations of the author's aim to infuse a little "jazz" into a dry subject.

HANDBOOK OF ANAESTHETICS. By J. STUART ROSS, M.B., Ch.B., F.R.C.S.E., Lecturer on Practical Anæsthetics, University of Edinburgh. With an introduction by HY. ALEXIS THOMSON, C.M.G., M.D., F.R.C.S.E., and chapters on Local and Spinal Anæsthesia by WM. QUARRY WOOD, M.D., F.R.C.S.E., and upon Intratracheal Anæsthesia by H. TORRANCE THOMSON, M.D., F.R.C.S.E. Edinburgh: E. & S. Livingstone, and New York, William Wood & Co., 1919.

THIS little volume contains 54 illustrations and its 214 pages of text comprise 21 chapters, some of which are as follows: Asphyxia or anoxemia, the shock of anesthesia, nitrous oxide, nitrous oxide and oxygen, ether, intratracheal ether, ethyl chloride, nitrous oxide and ethyl chloride, chloroform, chloroform and ether, accidents of anesthesia, sequelæ of anesthesia, choice of anesthetic, preparation of patient, posture of patient, and others indicated in the title page.

THE NEW PHYSIOLOGY IN SURGICAL AND GENERAL PRACTICE. By A. RENDLE SHORT, M.D., B.S., B.Sc. (Lond.), F.R.C.S. (Eng.), Examiner in Physiology for the F.R.C.S.; late Hunterian Professor, Royal College of Surgeons; Senior Assistant Surgeon, Bristol Royal Infirmary; Lecturer on Physiology, University of Bristol. Fourth edition, revised and enlarged. New York: William Wood and Company, 1920.

THE first edition of this little book appeared in 1911, and at once made a name for itself as a work of unusual merit. Each revision has enhanced its value, and these revisions have been so thorough that but little now remains of the original work. In the present edition the chapters on food deficiency, the blood and the spleen, surgical shock, the spinal cord, and the functions of the cerebral cortex are almost new; there is a new chapter on the heart; the chapter on digestion contains important additions; and almost every chapter bears the marks of careful revision. For students who have finished their work in physiology, and for practitioners who wish to see the value of much of the newer work on this subject, this book can be cordially recommended. The book is entirely practical and is, also, very readable.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held October 19, 1920.

DR. CARY EGGLESTON IN THE CHAIR.

THE program of the evening was contributed by the staff of the New York Hospital.

Report on Artificial Pneumothorax.—Dr. WILLIAM R. WILLIAMS made this presentation, in which he stated that pneumothorax as a therapeutic measure had been employed a number of times at the New York Hospital, though it had not been considered the treatment of choice. It was indicated in pulmonary tuberculosis, where it had been resorted to in patients who could not or would not go away, or who were too far advanced in the disease to be admitted to a sanatorium. They had not employed it in generalized tuberculosis, but only in cases in which the lesion was chiefly unilateral—and one did not often find strictly unilateral lesions in far advanced cases. The chief symptoms for which pneumothorax was indicated were excessively large cavities, excessive coughing or excessive hemoptosis; it was employed also in abscesses of the lung, with or without tuberculosis. In each of these groups they had utilized the procedure. The gas used was nitrogen, procured in a tank, under rather high pressure. Nitrogen was used in preference to oxygen because it was not absorbed as rapidly as oxygen. The essential points in the apparatus were measure of volume and pressure of the gas and a water manometer to indicate intrapleural pressure. A rubber tube and a hollow needle completed the apparatus necessary to perform artificial pneumothorax. The Robinson apparatus, which provided all these features, had been used, and had been found very satisfactory. Though there was no rule as to the site of the puncture, they had preferred the posterior portion of the lung, either in the axillary region or further back toward the spine. They employed local anesthesia and introduced the needle very carefully and slowly to avoid pleural shock. In introducing the needle the first thing to determine was when its point was in the pleural cavity. When the needle was in the pleural cavity the manometer showed rhythmical respiratory excursions, usually measuring from 2 cm. to 8 cm. negative pressure, with the water manometer. When the pressure became positive they ordinarily stopped the introduction of gas. The amount of gas introduced at first was from 200 c.c. to 500 c.c., though under special conditions one might use twice that much. The interval between injections was from two to five days at first; later it might be prolonged to a week or even longer. The *x*-ray had been used as a guide to indicate the progress being made, to show how extensively the lung was displaced, and to give evidence of adhesions when these were present. If the adhesions did not yield at all the operation was not repeated many times, but was usually stopped after two or three injections of the gas. It sometimes happened, in trying to introduce the gas, that so far as could be ascertained from the readings of the manometer, one could not enter the pleural cavity, and in those cases they did not introduce gas. Three or four attempts to find the pleural cavity at one seance was quite enough. The unfavorable results sometimes encountered with artificial pneumothorax were those associated with paracentesis, and these symptoms were considered as indications for stopping introduction of gas. Rarely there were the more serious accidents of shock and collapse, which had to be guarded against by care in technique. Sometimes the patient's temperature showed a slight increase for a day or two. One accident that might occur was emphysema into the mediastinum sufficiently extensive to cause death. Most of the patients in whom this procedure had been employed were extremely ill and the favorable results looked for were a decrease or cessation of cough, a fall in temperature and a decrease in expectoration, together with an improvement in the patient's general condition. They had frequently found these results very generously shown. They had had 20 cases in which patients suffering from pulmonary tuberculosis where the indications mentioned had been regarded. One of these was practically well. She had received 17 injections of gas and her weight had increased from 90 to 124 pounds. She had been followed for two years, was free from symptoms and was back at work, though he would not say that she was cured. Dr. Williams cited a number of cases, each with unfavorable prognosis under any method of treatment, which showed marked improvement under this treatment. Among these patients was a young man who, following artificial pneumothorax, was considered to be in very good condition. He was drafted into the army, and though the draft board was told that he had been subjected to pneumothorax they paid little attention to the statement. He was sent to camp, where he had to do some fairly hard work. After a few weeks he broke down, developed fever and cough, was kept in the hospital three or four weeks, and then was discharged with active tuberculosis. He came back quite ill and showed no improvement after that time. Four of the cases in this series showed such tight adhesions that attempts at pneumothorax were abandoned. Two of the series developed pyopneumothorax. One of these had received nine injections. As soon as the patient developed distinct pus the injections were abandoned, and he was sent to the country. He still had some pus in the chest but was feeling very well. One patient died as the direct result of the operation. They had successfully injected the gas on previous occasions. On this occasion the first attempt failed. A second attempt was made but did not succeed. The patient suddenly went into collapse, became comatose, had tonic spasms, his heart became rapid and weak, and he died about three hours after the operation. At autopsy it was found that the lung on which they were operating was adherent everywhere; at the point of puncture there was an ecchymosis on the pleural surface of the lung, apparently where the gas was admitted at the last puncture. There was a large cavity in the right upper lobe. There was no evidence of embolism, thrombosis or hemorrhage in the head. This accident was due, presumably, to some error in technique, but he was unable to offer a satisfactory explanation. In all the other cases there was a distinct subjective improvement following the production of artificial pneumothorax. The patients said they felt distinctly better and returned, asking to have the pneumothorax repeated. This, however, did not mean that they were all on the highway to recovery. He would not use this procedure as the method of choice, because he thought it much better to send the patients out of town and treat them under more favorable surroundings than were afforded in city hospitals. They had had seven cases of tuberculosis with pleural effusion, and had found at the end of three or four weeks, after giving two or three injections of gas, that the pleural effusion disappeared. They had also had several cases of lung abscess following pneumonia in which they used pneumothorax. All were subjectively benefited, but there was only one who was really cured. In pleural effusion without tuberculosis practically all the fluid could be removed without distressing the patient, and as the gas was slowly absorbed the patient gradually adapted himself to the changed pressure without discomfort. With reasonable care the danger in artificial pneumothorax seemed to be comparatively slight.

Dr. ALFRED MEYER said he would like to ask what brilliant draft board it was that passed a man as fit for service who had been subjected to artificial pneumothorax. There was a great difference in the way in which local anesthesia was administered. He had been greatly shocked at what might justly be called the brutal way in which patients were put on the table by some and the trocar introduced without any anesthesia at all, and without a re-examination. He did not think this indicated that the man doing the work felt his responsibility. In employing local anesthesia one must do more than merely produce anesthesia of the skin. Whether using adrenalin chloride, cocaine, or any other local anesthetic, the agent should be introduced drop by drop, deeper and deeper, until one reached the pleural cavity, and a few drops should be left in the pleural

cavity. One should then wait a few minutes until the anesthetic effect had been produced. That was the logical method of anesthesia and the only one he had used. He had known of three sudden deaths from the mere exploratory puncture of the chest, two of which occurred in hospitals in this city. He would never permit the puncture of a chest without local anesthesia and he had fortunately never had a sudden death from this procedure. No one should undertake this work without a manometer as a guide, both as to whether the pleural cavity had been entered and as to the amount of pressure of the gas. There should be a standardized method of reading the manometer. It was well to remember that as the water in the manometer stood at the zero point when at rest, when variations occur, the level will be the same distance above the zero mark on one side as it is below the zero mark on the other—in other words, the actual hydrostatic pressure, whether positive or negative, is obtained by doubling the reading on one side. It was a good rule never to have positive pressure in the early stages of the treatment. It should be remembered that one could never tell the exact condition of a lung, no matter how skilful one might be, and hence in the beginning of a treatment one should go very slowly and feel one's way, going from negative pressure slowly up to positive in successive inflations. In cases of severe hemorrhage one should be very certain that the compression was being made on the side from which the hemorrhage came, and in those cases one had to make positive pressure at the first sitting. With reference to the number of exploratory punctures, the physical and radiographical examination should be an indication, and every man contemplating performing pneumothorax should have a primary and secondary choice as to the location of puncture. He had heard of a man who made seven attempts in a first treatment. There should be a limit to the number of attempts made and certainly seven was away beyond a reasonable limit. He agreed with Dr. Williams that three or four punctures for locating the pleural cavity were quite sufficient for a primary pneumothorax. Personally, he had never made more than three attempts. Why was it that with some operators effusion and pyothorax were so frequent and with others so rare? He had a suspicion that in some instances the instruments were all put in alcohol and that during their use some alcohol was introduced into the pleural cavity; perhaps this was responsible for the effusion. Another possible factor was the high pressure, which might stretch adhesions to the extent of causing rupture, infection and effusion. Certainly the reason for the frequency of effusion in the experience of some and the infrequency in that of others must be sought in the technique. Dr. Meyer had been doing substitutive pneumothorax. He had employed this measure in hemothorax in leucemia and in carcinoma of the pleura. He substituted nitrogen for the fluid withdrawn. One patient with carcinoma whom he had treated in this way had obtained so much relief that she had begged for it.

Dr. MAURICE FISHBERG had been keenly interested in the patient mentioned by Dr. Williams who had died soon after the attempt to produce pneumothorax. He had had over one hundred cases under his care, and had not seen a fatality due to this procedure. He felt thoroughly convinced that if the technique were followed correctly there would be no such fatalities. He felt sure that there was some fault in the technique inasmuch as four previous punctures were made without causing any alarming symptoms. At autopsy the pleura was found completely adherent. It was possible that during the first four punctures the gas went into a bronchus and out of the mouth. It would seem that physical diagnosis or the radiographic examination or both, would have shown that in this case a second puncture should not have been made. The ecchymosis showed that the needle had entered a blood vessel. Those doing this work were careful not to introduce gas until there was a negative pressure of 8 to 10 cm. Dr. Fishberg said he had performed this operation more than a thousand times, in some cases extending over three, four or five years. It was true nitrogen was not as quickly absorbed as oxygen. At present they were using air for the reason that investigations had shown that within twenty-four hours the gas in the pleura was of the same composition as regards the proportion of oxygen and nitrogen irrespective whether atmospheric air was used or nitrogen. It was not necessary to use nitrogen and the use of atmospheric air saved trouble and expense. Some workers said they had only 5 per cent. of hydro- or pyo-pneumothorax, while others reported 50 or 75 per cent. effusions, 10 to 30 per cent. of which were purulent. When a patient got a purulent effusion the prognosis was exceedingly grave, though he had had under observation one patient who had lived over two years after developing pyopneumothorax. Five years ago, Dr. Fishberg recalled, he had said that pneumothorax was suitable to only 5 per cent. of cases with pulmonary tuberculosis, and to-day he could say that that 5 per cent. did better with pneumothorax than if pneumothorax had not been applied. At the Montefiore Hospital they made it a practice to keep patients on whom pneumothorax had been performed in the institution, and under observation as long as was necessary, even for several years. Still of many of them who were followed up, it was found that the majority had died, or remained sick, so that it was rather discouraging. The pneumothorax treatment of tuberculosis might be compared to the radium treatment of cancer. It was often encouraging when one took a tuberculosis patient with a temperature of 103 or 104 deg. Fahr., and introduced gas, to find within a week that the temperature had dropped to normal, remaining down perhaps three or four months. But in three, six, eight or twelve months, 50 to 75 per cent. would develop effusion. He could scarcely help questioning the accuracy of reports that showed only 5 per cent. effusions. As to the case that was accepted by the local draft board, they had had one man who was summoned from the hospital with a pyopneumothorax and was examined by the local draft board and accepted for service. They had made an affidavit at the hospital that he had been subjected to pneumothorax and with difficulty had succeeded in having the man discharged; but it took one month to get him out of the army, even with his pyopneumothorax.

Dr. WILLIAMS, in closing, said the local board was very fallible, but sometimes pneumothorax cases showed very few signs. What he resented was that they did not accept the statement of an accredited hospital. As to the fatality, he believed there was an error of technique but he did not know what it was; they thought all precautions against accident had been taken. The patient had had gas successfully introduced on previous occasions. There were some bands of adhesions, though, as the *x*-ray showed, they were justified in introducing more gas and collapsing the lung further. It was not an unusual experience to find adhesions that were gradually separated until satisfactory collapse of the lung was obtained. All were agreed that every possible precaution against accident should be taken; it was agreed also that this was a legitimate procedure for cases which otherwise would be almost hopeless.

Report on Three Cases of Splenic Anemia Treated by Splenectomy.—Dr. JOSEPH C. ROPER presented this report, in which he stated that one of these patients had been operated on twelve years ago and the other two five months ago. The first patient was admitted to the hospital at the age of 6 years, with a three years' history of malaria. The findings of importance were that the liver was 8 cm. below the costal margin; the spleen 14 cm. below the costal margin; erythrocytes, 2,336,000; leucocytes, 8,100; hemoglobin, 45 per cent.; normoblasts, 5,600, and megaloblasts, 1,200. Following operation the blood count was as follows: erythrocytes, 4,100,000; hemoglobin, 49 per cent.; leucocytes, 16,000; normoblasts, 64,000. Two years later the erythrocytes were 4,818,000; hemoglobin, 64 per cent.; leucocytes, 8,000; normoblasts, 1,000. Six years after the operation the erythrocytes were 2,640,000; hemoglobin, 56 per cent.; leucocytes, 17,000; normoblasts, 1,000. The fragility test six years after operation showed hemolysis beginning in 0.45 per cent. sodium chloride and complete in 0.25 per cent. sodium chloride. The spleen after removal measured 20 by 13 by 8 cm. and weighed 1420 grams. The capsule was smooth and the cut surface uniformly dark brown, showing no gross evidence of trabeculæ or follicles. Microscopically there was dif-

fuse connective tissue increase with almost no lymph tissue recognizable; only an occasional clump of lymphocytes; no structures resembling follicles; many cells with partly granular scanty cytoplasm and large oval or globular, pale-staining vesicular nuclei; many cells with eosinophilic granules and few with basophilic. The diagnosis was splenomegaly due to myeloidization. The other two patients were brothers 4 and 2 years of age, with negative family history. The older child had a history extending over two years, the younger over one year. The principal symptom was a moderate degree of jaundice, slowly increasing anemia and weakness, and increasing size of the abdomen. The four-year-old child showed on admission 2,500,000 erythrocytes, 17 per cent. hemoglobin, 9,000 leucocytes, 4,000 nucleated erythrocytes. Two days after splenectomy there were 3,600,000 erythrocytes, 16 per cent. hemoglobin, 20,00 leucocytes, 102,000 nucleated erythrocytes. Four days post-operative there were 3,280,000 nucleated erythrocytes. Seven weeks post-operative the blood showed 2,840,000 erythrocytes, 32 per cent. hemoglobin, 24,600 leucocytes and "many" normoblasts and megaloblasts. This child was transfused before splenectomy. Two days after operation the blood showed 5,000,000 erythrocytes, 43 per cent. hemoglobin, 75,700 leucocytes, 429,600 nucleated erythrocytes. Four weeks later there were 350,000 erythrocytes, 35 per cent hemoglobin, 30,000 leucocytes and 143,000 nucleated erythrocytes. The donor's cells were still easily distinguished from the patients in the last examination. Fragility tests in both cases showed hemolysis beginning at 50 and 55 and complete at 30. There was not excess of reticulated cells. The Wassermann was negative. The urine contained considerable urobilin but no bilirubin. The spleen of the four-year-old child measured 22 by 12 by 6 cm. The capsule was smooth, color normal and consistency increased. The cut surface was dark red. Malpighian follicles were observed microscopically; increase in connective tissue was not diffuse, but in strands occurring around diffuse blood vessels and as trabeculæ. The Malpighian corpuscles were not retained as such but lymphocytes were numerous. There was an increased blood content and a very large quantity of brownish pigment granules. The other spleen weighed 490 grams and showed the same microscopical conditions.

Dr. NATHAN E. BRILL asked Dr. Roper why he grouped the three cases which he had presented in the category of splenic anemia. It was pretty generally accepted, if he understood the literature on splenic anemia correctly, which he thought he did, that the disease was restricted to those cases which showed a spleen of large size, an anemia of the *chlorotic* type and a leucupenia, all associated with hemorrhages occurring most commonly from the mucous membranes, particularly from the stomach, from nasal mucosa and in the skin. In splenic anemia the anemia was definitely of the chlorotic type with greater relative reduction in the amount of hemoglobin than in the number of red blood cells, which rarely showed less than 3,000,000 per cubic millimeter. There were no extensive changes in the red blood cells and no embryonic forms. The enlargement of the spleen in these cases was progressive. Whether the terminal stage of this disease resulted in so-called Banti's disease, as suggested by Osler, he did not care to discuss. Banti's disease, however, did not represent a distinctive clinical and pathological entity, but it might well be a phase of a pre-existing associated or combined disease of blood, liver and spleen. None of Dr. Roper's cases presented the distinctive data thus described as characterizing splenic anemia; all showed hyperleucocytosis, the reverse of leucopenia, all showed marked changes in the red blood cells, including forms suggestive of bone marrow stimulation, indicating possibly von Jaksch's anemia. In fact, one of the cases, reported as having a spleen which was transformed into a myeloid spleen, and having a large number of myelocytes in the blood together, with embryonic forms of red blood cells, might have been an instance of myeloid leucemia. Dr. Brill did not wish to say that it was, but suggested this as a possibility. From the pathological viewpoint cases of splenic anemia showed a general fibrosis of the spleen, including the reticulum associated with its encroachment on the Malpighian bodies, even obliterating them, distension of the sinuses, and desquammation of the endothelium of the sinuses. These changes were not reported as having existed in the extirpated spleens of these cases. Hence it was that he would like to ask Dr. Roper to explain why he had classified these cases in the group of splenic anemia.

Dr. ELI MOSCHCOWITZ said that assuming that Dr. Roper was correct and that at least two of these cases were cases of splenic anemia, he was glad that Dr. Roper did not say that the patients were "cured." A few years ago he had studied the question of the value of splenectomy in Banti's disease and had expressed scepticism as to its value in that disease. For this he had been taken to task. His scepticism was based upon the fact that patients with Banti's disease lived for many years, even for ten or twelve years, even when splenectomy was not performed. He had been much pleased recently to read in the "*Archives of Surgery*" an article by Harvey Cushing in which he reported two cases of Banti's disease. In one splenectomy was performed in 1898. This case had gone down twice in the literature as a cured case of Banti's disease. Dr. Cushing reported him as suffering at present from the same symptoms as before splenectomy was done. In the other case splenectomy was perfomed, he believed, twelve years ago and the patient was still suffering from the same symptoms. Recently there died at Mount Sinai Hospital a patient on whom splenectomy had been performed by Dr. Gerster in 1909. That case had also gone into the literature as a case of Banti's disease cured by splenectomy, yet the patient died of symptoms that could be interpreted as those of the terminal phase of Banti's disease. He had anemia and ascites, and all the evidence pointed to his having died of Banti's disease. The report of a case of splenic anemia as "cured" by splenectomy, even after five years from the time of the operation, was not, in the speaker's opinion, of much value.

Dr. RALPH G. STILLMAN said when the third case had been first reported they had been inclined to make the diagnosis of von Jaksch's anemia. That inclination had been strengthened by the fact that the histological picture in the spleen was very similar to that seen in two other cases which were studied at the same time. But as time went on and the patient was followed doubt had arisen as to the correctness of that diagnosis. Pearce had expressed the opinion that the case was one of hemolytic icterus. A satisfactory diagnosis was still lacking. Whether the other two cases could be classified as splenic anemia was open to discussion and depended somewhat upon the understanding of that term. He wished to mention the fact that although some of the patients were by no means cured by the operation, yet a remarkable improvement often took place and they were able to live comfortably for years. The older child operated upon four or five years ago, he had seen at fairly frequent intervals; she was not well but had improved. With the irregular use of iron and arsenic her hemoglobin rose and fell and at times the nucleated red cells mounted to very high figures. These nucleated red cells had not been absent from her blood at any examination made since her operation, with the exception of one made during her last admission to the hospital for phlebitis, and the question naturally arose as to whether the infection had anything to do with their absence. Apparently in this case the splenectomy had removed some inhibitory influence upon the bone marrow, or at least had produced some change in the body activity so that either the red cells were produced much more rapidly or they were injected into the circulation much more rapidly than before the spleen was removed.

Dr. DAVID BOVAIRD called attention to a paper by W. J. Mayo, published in the second volume of "Contributions to Biological Science," in honor of Sir William Osler's seventieth birthday, which was both radical and thought provoking. Briefly Dr. Mayo stated that cases of splenomegaly were potential cases of splenic anemia, and that as the onus of these conditions rests upon the spleen, even though the etiology is not clear, the spleen had best be removed. In some cases of chronic enlargement of the spleen, known to be luetic and which did not respond to anti-luetic treat-

ment, following the removal of the spleen the patient became responsive to anti-luetic treatment. It was further stated that von Jaksch's anemia was an infantile type of splenic anemia, the various types of the blood picture in this disease being simply manifestations incidental to the age of the patient. Mayo went still further and discussed the possible relation of enlarged spleen to cirrhosis of the liver, and stated that in atrophic cirrhosis of the liver splenectomy had alleviated the symptoms. The paper was the most radical one he had seen and presented arguments for the removal of the spleen in various forms of splenic anemia and atrophic cirrhosis of the liver. Dr. Bovaird said that as we had progressed we had separated one type of disease after another from the group of diseases formerly considered as belonging to splenic anemia, until there was left a fairly definite group of cases which, clinically, we know as splenic anemia. The pathology in such cases seemed to be mostly a fibrosis. But as Dr. Roper had noted in one of his cases there was a somewhat different pathology, a condition resembling a myeloid spleen, so doubtless we would eventually separate still other types of cases from the group we now recognized as splenic anemia, until we would have a group that agreed in pathology and which clinically we would recognize as an entity. As yet the subject was still complicated.

Dr. ARTHUR F. CHACE expressed the opinion that undoubtedly splenectomy was of value in the first stages af splenic anemia but he questioned whether it was of much value in the secondary stage when the liver had become involved. He thought that in cirrhosis of the liver the Mayos had given up removing the spleen, and other surgeons seemed to be of the opinion that nothing was gained by removing the spleen in cirrhosis, though it might be of value in the first stages before ascites had developed. He had watched one case for five years to determine whether or not operation was advisable. Finally the patient became so anemic and weak that it was decided to operate, and after operation the blood picture changed for the better. He recalled another case in which results following splenectomy were favorable, but there was a possibility of this case being one of hemolytic jaundice, in which condition splenectomy was more favorable than in splenic anemia.

Dr. LOUIS SHAPIRO quoted the conclusions from an article on Banti's disease, by Dr. Charles Norris, Dr. Douglas Symmers and himself, published in the *American Journal of Medical Sciences* in 1917, in which they showed that Banti's disease was neither an independent clinical entity nor anatomical entity, and expressed the opinion that this designation should be eliminated from the nomenclature of splenic pathology, giving the reasons for this statement. In this article they concluded further that the histological changes in the spleen in the condition described by Banti were identical with those due to syphilis. The lesion was a chronic diffuse interstitial splenitis attended in certain instances by sclerosis of the Malpighian follicles. Banti and his followers had attached great significance to the latter finding. As a matter of fact, sclerosis of the Malpighian follicles was characteristic only of recessive status lymphaticus, in which it occurred with unfailing regularity, and in the spleen of so-called Banti's disease it was but a coincident histological change.

Dr. ROPER, replying to Dr. Brill's question as to why he had classified these cases as splenic anemia, said they were obviously not cases of hemolytic jaundice or Gaucher's disease. There was a growing tendency to classify cases which ordinarily would come under the name of von Jaksch's disease as an infantile form of splenic anemia. The blood in children as young as these might easily show variations not seen in the adult types, but this should not exclude them from the classification. Regarding Dr. Stillman's suggestion that the first case might be one of hemolytic jaundice, Dr. Roper felt that had it been there would have been very definite improvement after six years. The most brilliant results in splenectomy had been obtained in hemolytic jaundice. This case could not be classified as definitely improved after six years.

Notes on the Use of the Fluoroscope in Gastro-enterology with Reports.—Dr. ARTHUR L. HOLLAND made this contribution, in which he said that owing to the demands made upon the staff of the New York Hospital during the war, and particularly on that of the *x*-ray department, the fluoroscope was called upon much oftener than it had been in the diagnosis of gastrointestinal disease. It was some time before they had acquired sufficient confidence to put cases through to operation to treatment without a further confirmation by plates. As they had progressed, however, they had found that in a large number of cases they could do as well, or better than they had been doing with the plate method. Duodenal ulcer, for instance, they were early able to demonstrate in nearly every case. They now gave the preference to the fluoroscope, reserving the plate method for those interesting cases in which they wished to preserve records. Their former report on this subject had occasioned some criticism and hence the present report. For this report they had taken 100 consecutive cases from the records of their two hospital services, examining first the records indexed under post-pyloric or duodenal ulcer. Of these there were 31 that were diagnosed at operation by the surgeons as post-pyloric or duodenal ulcers; 28 of these had been correctly diagnosed by the fluoroscope. In three cases the exact location of the lesion was not indicated. There were 12 cases in which the diagnosis at operation was gastric ulcer. Of these they had fluoroscopically diagnosed 10 accurately, approximately 83 per cent. There were 13 cases that were operated upon and diagnosed by the surgeons as carcinoma. In 10 of these they had given their opinion that the pathology found fluoroscopically furnished evidence of carcinoma. In three cases the fluoroscopic reports were not clear and definite. This gave thus far 56 cases, 48 of which, or 85.7 per cent., were diagnosed fluoroscopically with approximate accuracy. In order to get some idea of what their percentage of correct negative diagnoses was, Dr. Fellows, who had gone over the records for him, searched out the cases that had been operated on for extragastric lesions, in which they had given negative diagnoses for organic disease of the stomach or duodenum. Chronic appendicitis gave the largest number in the extra-gastric lists. There were 22 such cases, in 19 of which they had given a correct negative diagnosis for disease of the stomach or duodenum. Eight cases were indexed under operations for adhesions, in all of which their negative fluoroscopic diagnosis for organic disease of the stomach or duodenum was upheld by the surgeons. In all but one the fluoroscopic findings suggested adhesions. In other words, they were sustained in their negative diagnosis 42 times out of 46. This gave a record of 90 per cent. correct diagnoses, with 10 per cent failures or doubtful results. Dr. Holland discussed these failures and showed why some of them had occurred. The fluoroscopic room was small, badly ventilated, and superheated, and most of the observations were conducted before a section of twelve or more students, and at times hurriedly. Some of the patients were bedridden and had to be examined in the recumbent position, which was always difficult. While making this research they had been able to make a few notes on some of the clinical data given in the histories. For instance, in duodenal or post-pyloric ulcer, out of 28 cases there were 10 in which the histories were typical; in eight the histories were strongly suggestive, six were irregular, and in four the clinical data did not in any way uphold or even suggest the diagnoses. In 21 out of the 28 the acid values as shown by gastric analysis were high; in only four were the acid values below normal. In only one was free hydrochloric acid absent. The syndrome of post-pyloric ulcer was therefore fairly reliable, but where it failed it did so so completely that the aid which the fluoroscope gave was not to be ignored, and doubly armed with the clinical, laboratory and the fluoroscopic findings, one should have no difficulty in making in practically 100 per cent. of the cases a positive or a negative diagnosis. There were few other internal diseases in which this could be done. It was impossible to place a lesion accurately by clinical and laboratory methods alone; judging from their experience, the fluoroscope was the most reliable means they had for this purpose.

Dr. CARY EGGLESTON expressed the opinion that the majority of them would not be as successful as Dr.

Holland had been. The interpretation of a condition by means of the fluoroscope to the uninitiated was not a simple procedure, but there was hope that they might be able to master its use and if this were done, it offered one advantage over radiographs, which required time and were often more difficult to obtain.

Dr. GEDIDE A. FRIEDMAN said there was no doubt that the fluoroscope was of great value for the diagnosis of peptic ulcer, but it must not forgotten that the history of the patient was the chief aid for diagnosis of gastric or duodenal ulcer. It was true, as stated, that examination of the gastric contents were not valuable for the diagnosis. It was equally true that in a very small percentage of cases there was no definite history pointing to either gastric or duodenal ulcer. Every one knew that in 75 per cent. of patients who visited gastroenterological clinics, peptic ulcer might be suspected. It was his belief that radiologists took very careful histories from the patients. He had been at the Vanderbilt Clinic for ten years and could guess pretty well from the history alone as to the presence of an ulcer. Only occasionally he was wrong. This being true, a large percentage that presented themselves for fluoroscopic examination should have peptic ulcer. But how was it possible to diagnosticate ulcer from fluoroscopic examination in the majority of cases? The chief roentgen sign for ulcer of the duodenum was believed to be the deformed cap. But one found a similar deformity in gallbladder diseases. Spasticity of the stomach did not mean necessarily ulcer, because this had been present in many other conditions. Dr. Holland said that a perforated gastric ulcer was detected under the fluoroscope and that this diagnosis was confirmed at operation. Any one who was doing much gastrointestinal work would frequently diagnose a perforated ulcer correctly from the history and the physical examination alone. It was true that the appendix might be visible under the fluoroscopic screen. But this did not always mean appendicitis, as he was convinced from the negative findings of the pathologist in such cases. Adhesions around the appendix might be found without actual pathology in the latter. One must keep in mind that the appendix was a muscular organ, and, as such, passed through atonic and spastic states. Retention of the contrast meal in the appendix might be found 96 hours later without actual pathology in the appendix. On the other hand, concrements had been diagnosed in the appendix because of spasticity of the musculature, and when the surgeon did not find stones, the pathologist was not able to detect appendicitis. From all that was said he would not be convinced that it was possible to make a correct diagnosis in 100 per cent. by means of fluoroscopic examination alone.

Dr. GEORGE WOOLSEY said he was glad to bear witness to the value of the fluoroscope in skilled hands as he had seen it used by Dr. Holland. Last May, in a paper he read before the Surgical Section on the "Results of Operation in Gastric and Duodenal Ulcer," he had mentioned a series of cases that had been radiographed by Dr. Cole, a large number of radiographs being taken in each case. These cases, some 20 in number, were also fluoroscoped by Dr. Holland, and afterward operated upon in Bellevue Hospital by himself, and the results of the radiographic and fluoroscopic diagnoses confirmed. There was no advantage on the part of the radiographic plates over the fluoroscopic findings. Since that time they had depended more and more upon the fluoroscope, so that in cases sent over from Cornell to Bellevue for operation the fluoroscopic examination was all that was made for diagnosis before admission to the hospital. In one or two of these cases, which were rather difficult of diagnosis, they made the observation that the plates did not show the lesion which was confirmed at operation. One of these cases was operated upon previously and only adhesions found. In this case Dr. Holland was able to demonstrate a perforating ulcer on the posterior surface near the lesser curvature, about five inches from the plyorus. This could be seen only with the patient in the oblique position and was not shown by the ordinary antero-posterior plates. Another post-pyloric ulcer was not shown by the *x*-ray plates. In addition to its efficiency in demonstrating gastric and duodenal ulcer the fluoroscope was simpler to use and cheaper than the *x*-ray plates. He had watched the fluoroscopic examination and then operated, and could bear testimony to the great value of the fluoroscope in the hands of an expert in the diagnosis of gastric and duodenal lesions.

Dr. I. SETH HIRSCH said it would seem that one of the benefits of the war was the revelation to the general profession of the value of the fluoroscope. Where formerly it was an instrument in the hands of the specialist, it was now being generally adopted by the clinician to meet the demands of every day clinical diagnosis. And yet the fluoroscope was no new instrument, but for fifteen years had been actively used in the hospitals of the city under his direction in diagnosis of diseases of the chest and gastrointestinal tract. There was no necessity for making a distinction between the fluoroscopic and the radiographic examination, nor of balancing the value of one form of examination against the other, any more than there was anything to be gained from balancing the value of percussion against auscultation in the examination of the chest. A complete roentgenological examination must include both the examination by the fluorescent screen and the photographic plate. While fluoroscopy had its advantages, it also had its numerous disadvantages. The two procedures supplemented each other. Of the two methods of examination, however, it must be conceded that, in spite of the simplicity of its technique, the reading of the fluoroscopic image was far more difficult. It was continually observed that in the eagerness to adopt this valuable diagnostic procedure, it was utilized with insufficient understanding of the meaning of the images obtained. It was surely as difficult to read the Roentgen image as the pathological slide and it needed no argument that it required more than a microtone and miscroscope to make pathological diagnosis. The fluoroscopic examination was absolutely essential in the study of the gastrointestinal tract. It was essential in the examination of all the movable organs, lungs or heart, etc. The varying phases of the functional activity of an organ could not be completely studied from plate examinations, no matter how made. The attempt to make an examination of the gastrointestinal tract from plates alone was like attempting to diagnose an ataxic gait from a single photograph. In the gastrointestinal tract a complete fluoroscopic and plate examination must be made. There were appearances which could not be correctly analyzed on the plate, and there were others which could be successfully interpreted only by a fluoroscopic examination. If one were limited by circumstances to one method, the fluoroscopic would by all means be the choice. The great value of the Roentgen ray in the diagnosis of ulcer of the stomach and duodenum and the high percentage of correct diagnosis possible by this means could not be denied. And yet such statistics as were given to-night were of no great value in demonstrating the accuracy of this method, because the examiner possessed a clinical knowledge of the cases. It was impossible to deny the influence of the clinical knowledge of the case upon the one making the examination. One often saw what one wanted to see. He differed with the opinion of the reader of the paper as regards the equipment of the individual who was to make the fluoroscopic examination. The individual who made the ideal fluoroscopic or radiographic examination was the one who knew nothing of the clinical aspect of the case. The roentgen findings were to be reported in accordance with the established data of the art, and an interpretation based on these findings only was to be made. It was then for the clinician to take the roentgen report and in connection with the history and his own clinical data to build up a final diagnosis. The vast majority of organic lesions of the gastrointestinal tract could be diagnosed on roentgenological findings alone. But only a small percentage of the cases examined had organic lesions and the functional diseases of the gastrointestinal tract could be diagnosed on roentgen findings alone.

Dr. L. T. LE WALD said he had examined about 10,000 cases a year and stated that neither method alone was sufficient. He used the fluoroscope and also asked the patient questions, and subjected the patient to palpatation, etc., if necessary. If Dr. Holland had confined his remarks to duodenal ulcer alone they would not have provoked so much criticism because in duo-

denal ulcer per se the fluoroscopic examination was as important as the plate method. However, there should be no conflict between the radiographic and the fluoroscopic methods, and if the internist was going to use the fluoroscope he must also use the plates. When it came to tumors, etc., one had an entirely different problem which could be worked out only by careful plate study. Dr. Le Wald declared that he had seen disaster follow only fluroscopic examination where a complete examination of the digestive tract by the plate method was not carried out. If the roentgenologists' work was confined solely to the negative or positive diagnosis of duodenal or gastric ulcer, the problem would be a very simple one. Unfortunately, the cases which seemed to fall to his lot came for a diagnosis of some intra-abdominal lesion, so that after excluding a duodenal ulcer, for example, his troubles had just begun. A prolonged study of the entire digestive tract and other abdominal and thoracic organs had to be made, together with perhaps a combined urological and *x*-ray examination. The status of the roentgenologist had been definitely fixed by the fact that the Association of American Medical Colleges required that roentgenology must now be taught as a specialty in all class A medical schools.

Dr. Holland, in closing, said that he thought the grounds on which some of the objections were based were not quite correct; he thought he had made it plain that no comparison of fluoroscopy and radiography had been attempted. In the New York Hospital the fluoroscope was used during the early part of the war because the *x*-ray department had been reduced and they had found that as clinicians, using the instrument as a clinician used a stethoscope, they could get considerable help from it. The surgeons connected with the Hospital had confirmed their diagnoses in such a large percentage of cases that they too had come finally to have great confidence in it as a diagnostic means. Percentages, however, had very little value in themselves in a matter of this sort. As to those extra-gastric lesions, such as gall-bladder disease and appendicitis, he did not for a minute consider the fluoroscope; that he had used it with these cases that had been operated on for gall-bladder disease and appendicitis simply to prove their negative diagnoses, but at the same time in perhaps one-half of these cases they had by interpreting the indirect signs, such as increased peristalsis and spasm, been able to call the surgeons' attention to the fact that there was trouble somewhere else in the abdomen. This had been some help, as they were thus forearmed. As to considering the clinical histories, it was inevitable that they should ask some questions of the patients. After all, one could not hope to do much with the fluoroscope outside of the stomach, duodenum, and the colon after a barium enema. Dr. Holland said that he bowed humbly to Dr. Hirsch's tremendous experience. Dr. Holland said that he did not know who had done the *x*-ray work in the case in which Dr. Woolsey operated, but that he had done the fluoroscopic work and was able to tell accurately where the trouble would be found. And very often this same thing had occurred—the surgeons finding the lesion that they had by the fluoroscope predicted where it would be found.

Observations on Asthma and Hay Fever.—Dr. ALBERT VANDER VEER, Jr., presented this contribution in which he said that the observations, conclusions, and statistics from which this paper was written were founded on about 2,000 case histories of hay fever and asthma of Dr. Robert A. Cooke and the writer. No attempt was made to cover the entire subject; the present communication was intended simply as a statement of the present status of knowledge of these diseases. Although we had a rational and successful treatment for hay fever, he thought the laiety were not reaping the full benefit from it. They were still using timothy and ragweed pollens to make up their extracts for the early and late types of hay fever. Many years ago they had abandoned the use of mixed pollens. Occasionally a case needed an extract from golden rod, corn, dandelion, or one of the less important pollens, but at least 95 per cent. of the cases came under the first two mentioned. Their preparations were saline extracts of the pure pollens, standardized according to the amount of nitrogen contained, and given in gradually increasing doses up to the end of the season, a total of fifteen to twenty injections at five to seven day intervals. They had been unable to get satisfactory results by a course of injections stopping before the season opened, as the immunity began to decrease shortly after any injection, and they found that after a week or ten days it dropped to a point where the patient was no longer properly protected. As yet they had been unable to produce permanent immunity, although some cases would go for several years without treatment. The percentage of satisfactory results ranged from 70 to 75, varying with the severity of the year, the extract used, and the intelligence of the patient treated. Local reactions were slight and might be disregarded. Constitutional reactions were rare, but were much more unpleasant and should be guarded against by every possible precaution. A general urticaria was the form they usually took. They might be almost entirely controlled by injections of epinephrin. . Dr. Vander Veer presented the replies to a questionnaire sent out to patients each year. He received 379 such replies in 1917; 400 in 1918, and 473 in 1919. It seemed to him that these figures were large enough and the percentages ran close enough to say that on the average 25 per cent. were entirely relieved, 50 per cent. were quite comfortable, 15 per cent. were slightly benefited, and 10 per cent. showed no improvement. This gave about 75 per cent. which were considered quite satisfactory. Factors which at present they were unable to control would eventually enable them to improve this percentage. These were the preparation of a stable extract which would last through the season without deterioration and, secondly, some method of more accurately gauging the maximum dose a patient might take without developing a constitutional reaction. The advance in our knowledge of asthma had been greater during the past few years than with hay fever. The relatively simple cases, hypersensitive to one or more animal epithelia, or to one or more foods, were easily controlled by removing the offending animal or abstinence from the food. The more difficult cases were those of multiple sensitization and those with a complicating bronchitis or other infection. Asthma due to food alone was a relatively rare occurrence. Less than three per cent. of all cases would be found due solely to food. He thought they had been led astray on this matter by the patient's own histories, as practically all asthmatics were worse after a large meal and were apt to blame their trouble on this or that food, which, strange to say, they were at times able to eat with impunity. Several years ago they had found that many asthmatics gave a reaction to dust collected from their houses and bedrooms. These reactions were usually as constant and positive as those due to pollens and unmistakably pointed to the presence of a substance which could conceivably cause the trouble. The more they had investigated his subject the more such cases they discovered until now they formed a large group in the total number. Dust was a conglomeration of many substances, among them talcum powder, chicken feather dust, mattress dust, pollen and animal epithelia. When a positive reaction to dust was obtained they endeavored to make up extracts from each possible source of trouble, test them out, remove such as gave positive reactions and then, after a thorough house cleaning, again test with extract of the whole dust. If the reaction was now negative it proved that the source of possible trouble had been removed and the patient, as a rule, was relieved. They had occasionally made up extracts for treatment from the dust where there was some objection to following out the usual procedure, and the results were fairly successful. though not as satisfactory as removing the cause of the trouble. The cases which at present gave the most trouble and in which they had achieved the least were those with negative skin reactions to all these tests. These, as a rule, were people past middle age, with negative family history for allergy, and a complicating chronic bronchitis or other infection. The course of treatment here was long and discouraging. Vaccines were made from the sputum and injections were given over long periods of time. All chronic infections of tonsils, sinus, teeth, etc., were given careful attention. These patients were often benefited by change in climate and this should be tried, but not until other measures

had failed. The speaker called attention to the fact that until recently there had been no facilities for the treatment of asthma and hay fever among the poor. Gradually such clinics were being started. They had been working with such a clinic under the First Medical Division of the New York Hospital in conjunction with the Cornell Medical School. Here they had a laboratory well equipped for the work and a visiting nurse whose services were very essential in the handling of the so-called dust cases. Asthma was a fairly prevalent disease, the cause of an immense amount of suffering and tremendously expensive to the community, due to the time lost from work. We had now a rational fairly successful method of treating it and were justified in hoping for great advances in the future. Several illustrative cases were cited.

Dr. FENTON B. TURCK said that some of the experimental work that he had done in his laboratory was of interest in connection with the subject of hay fever and asthma. He had observed that when autolyzed lung tissue was injected into the bronchi of animals there was always an immediate response in the shape of rhinitis. If very high concentrations of autolyzed lung tissue were injected, the animals immediately developed rhinitis, and, following this, severe respiratory symptoms, and died in an exceedingly short time. If the autolyzed lung tissue were injected in lower concentrations, the animals developed the same symptoms in a lesser degree and recovered. The reason of this was that a reaction took place in the lung itself. In all cases of rhinitis a reaction took place in the lungs and gradually manifested itself in other portions of the respiratory tract. If one side of the bronchial tree were injected, the lungs on both sides immediately became engorged. The proteolytic enzymes, erepsin, trypsin, and pepsin found in all animal and vegetable tissue seized upon the cells of the body, autolyzed the tissues, and a reaction followed due to the breaking down of the animal's own tissues. The dust of human origin from pillows and beds was an exceedingly interesting factor in the causation of these respiratory affections. Animals were very susceptible to minute quantities of homologous autolyzed tissue. He had observed that if healthy control animals were placed in the same cages with those animals that had their paws coated with autolyzed homologous tissue, the control animals soon showed a reaction rhinitis, bronchial affections, and pneumonias. It was by demonstrated biological reactions as well as by empirical facts that the scientific aspects of this subject could be explained. Active immunity might be established by injecting very minute quantities of ferments to cause autolysis, or by chloroform as a cauterizing agent; this was followed by a specific passive immune serum, made by injecting horses with human antigen, thus combining active with passive immunization.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OREGON STATE BOARD OF MEDICAL EXAMINERS.

July 6, 7, 8, 1920.

ANATOMY.

1. Describe the first part of the duodenum; give relationships.
2. Name the branches of the abdominal aorta.
3. Bound and give contents of the popliteal space.
4. Locate the prostate gland and give relationships.
5. Describe the subclavian artery, naming the branches.
6. Give origin, insertion, action, and nerve supply of the tibialis anticus muscle.
7. Describe the blood supply of the kidney.

PHYSIOLOGY.

1. What is the function of the red corpuscles? State their number and their variation with altitude.
2. Describe the lymphatic system and state what factors control the lymphatic circulation.
3. Give the names and state what kind of nerves the sixth and eleventh cranial nerves are. What does each supply?
4. Name the four divisions of the circulatory system and describe how the circulation of the blood is regulated.
5. Describe the physical properties of (*a*) lymph and (*b*) chyle.
6. What produces the second sound of the heart, where is it best heard, and what events in the heart's action are coincident with it?
7. Describe the phenomena which occur when muscle is in a state of activity.
8. State the functions of the spinal cord and enumerate its special centers.

BACTERIOLOGY AND HISTOLOGY.

1. Define bacteria: (*a*) Give method for recognition and cultivation; (*b*) Conditions most favorable for growth, and the different ways of entering the body.
2. What are pyogenic bacteria? Name the important pathogenic anærobes.
3. Define germicide, antiseptic, asepsis, sterile, disinfectant, spore, flagellum, and mycelium.
4. State the method of sterilizing the following: Fluid culture-media, test tubes, rubber gloves, rubber stoppers, cotton plugs or stoppers.
5. Where is the gonococcus usually found? Describe its characteristics; Give in detail a method of staining it.
6. Describe fibrous tissue and yellow elastic tissue, and state where they are found.
7. Define the following terms: (*a*) Neurone; (*b*) Dendrite; (*c*) Axone; (*d*) Implantation cone; (*e*) axis cylinder.
8. Describe Peyer's patches and give location.
9. Name the structures found in the portal canals of the liver.
10. (*a*) Name the stages into which the process of caryokinesis is divided. (*b*) Describe the formation of the achromatic spindle.

MATERIA MEDICA AND THERAPEUTICS.

1. Give the therapeutic uses of iodides, and when contraindicated.
2. Give the dosage and action of three drugs used to retard the heart's action. Name three that increase the heart's action.
3. State your medicinal procedure in a case of eclampsia with convulsions.
4. Write a prescription for a cough mixture containing a sedative-expectorant, a hypnotic, and a cardiac stimulant.
5. Mention the indications for and against ether and chloroform anesthesia.
6. (*a*) Name three vasomotor depressants, three vasomotor stimulants, and give the dosage of each. (*b*) Name three mineral cathartics, three vegetable cathartics, and give dosage of each.
7. In a child eight years of age find a case of diarrhea: Outline your treatment and diet.
8. How do you decide the donor in giving a blood transfusion.
9. What is phagocytosis? Define leucocytosis, emmenagogue, and hydragogue.
10. Name three suitable remedies for croup and give your method of treatment.

CHEMISTRY AND TOXICOLOGY.

1. Give diagnosis and treatment of acute poisoning with phosphorus. How would you test for phosphorus?
2. How does wood alcohol differ from grain alcohol? Give formulæ. How would you treat a case of poisoning by wood alcohol?
3. What two remedies are especially indicated in chronic lead poisoning? Describe the action of each in said condition.
4. Complete the following equation and describe the properties of the substance formed: $Hg. Cl_2 + 2KI = ?$
5. Define anhydrous, deliquescent, efflorescent.
6. Give the differential diagnosis between convulsions due to strychnine poisoning and tetanic convulsions.
7. Describe a test for lactic acid in the stomach contents.
8. Describe a chemical test for detecting the presence of blood in urine.
9. What is uric acid, and from what source in the human economy is it derived? Describe a test for uric acid.

10. What are enzymes? Give chemical characteristics.

ANSWERS.

ANATOMY.

1. THE DUODENUM is the first part of the small intestine, and is so called from being about twelve fingers' breadth in length, is about eight to ten inches in length. It consists of four portions, from the position of its course—ascending, descending, transverse, and terminal ascending. The *first* or *ascending portion* is about two inches in length, and ascends to the neck of the gall-bladder. It is completely invested by peritoneum for about an inch.

Relations of the first part: In front—Liver, gall-bladder. *Behind*—Bile-duct, vena portæ, hepatic artery, gastroduodenal artery. *Below*—Head of pancreas.

2. The *branches of the abdominal aorta* are: Celiac axis, inferior phrenic, suprarenal, renal, spermatic (or ovarian), superior mesenteric, inferior mesenteric, lumbar, middle sacral, and common iliacs.

3. BOUNDARIES OF THE POPLITEAL SPACE. *Externally, above:* By the biceps. *Externally, below:* By the plantaris and external head of the gastrocnemius. *Internally, above:* By the semimembranosus, semitendinosus, gracilis, and sartorius. *Internally, below:* By the inner head of the gastrocnemius.

Contents: Popliteal artery and vein, external and internal popliteal nerves, termination of external saphenous vein, small, sciatic nerve, articular branch from obturator nerve, lymph glands, and loose adipose tissue.

4. The prostate gland surrounds the neck of the bladder and first part of the urethra in the male. Its base is attached to the base of the bladder, and its apex is in relation with the posterior layer of the triangular ligament and the compressor urethræ muscle. The posterior surface is in relation with the rectum and is about an inch and a half from the anus.

RELATIONS OF PROSTATE. *Anteriorly:* Symphysis pubis, anterior ligaments of bladder, branches of dorsal vein of penis. *Posteriorly:* Rectum. *Laterally:* Levator ani. *Base:* Surrounds neck of bladder, seminal vesicles, and vasa deferentia. The *apex* rests on triangular ligament.

5. THE SUBCLAVIAN ARTERY. On the right side, this artery arises from the innominate artery; on the left side it arises from the aorta. It passes outward to the lower border of the first rib, where it becomes the axillary artery. The artery is divided into three parts, by the scalenus anticus muscle; the first part being internal to the muscle, the second part behind the muscle, and the third part extending from the outer margin of that muscle to the lower border of the first rib. Hence the arteries differ in their first portions only. The *branches* are: The vertebral, thyroid axis, internal mammary, and superior intercostal.

6. TIBIALIS ANTICUS. *Origin:* The upper and outer two-thirds of the shaft of the tibia, the interosseous membrane, and the intermuscular septum. *Insertion:* The internal cuneiform bone and the base of the first metatarsal. *Action:* Flexor of the foot. *Nerve supply:* The anterior tibial.

7. *Blood vessels of kidney.* "The renal artery enters the kidney at the hilus, and divides into branches that pass toward the cortex, then turn over and form incomplete arches in the region between cortex and medulla. From these arches vessels pass to the surface which are called the interlobular arteries; they give off vessels at right angles, which are the afferent vessels of the glomeruli; a glomerulus is made up of capillaries. From each a smaller vessel (the efferent vessel of the glomerulus) passes out, and like a portal vessel on a small scale, breaks up once more into capillaries which ramify between the convoluted tubules. These unite to form veins (interlobular veins) which accompany the interlobular arteries; they pass to venous arches, parallel to, but more complete than, the corresponding arterial arches; they ultimately unite to form the renal vein that leaves the hilus. These veins receive also others which have a stellate arrangement near the capsule (venæ stellulæ). The medulla is supplied by pencils of fine straight arterioles which arise from the arterial arches. They are called arteriæ rectæ. The efferent vessels of the glomeruli nearest the medulla may also break up into similar vessels which are called false arteriæ rectæ. The veins (venæ rectæ) take a similar course and empty themselves into the venous arches. In the boundary zone groups of vasa recta alternate with groups of tubules, and give it a striated appearance."—(Halliburton's *Physiology.*)

PHYSIOLOGY.

1. The *function of the red corpuscles* is to carry oxygen from the lungs to the tissues of the body. The *number* of the red corpuscles is about 5,000,000 in the male, and about 4,500,000 in the female, to each cubic millimeter of blood. At high altitudes the number of red corpuscles is increased.

2. The lymphatic system consists of: lymphatic glands, lymph vessels, perivascular lymph spaces, the lymph canalicular system, the pericardial, pleural, peritoneal, and synovial cavities, and the lacteals.

The lymphatic circulation is, strictly speaking, not a circulation at all, since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, where the left internal jugular vein also enters. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.

The forces concerned in the circulation of the lymph are: (1) The pressure of the blood in the blood-vessels; (2) thoracic aspiration; (3) muscular contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

3. The *sixth cranial nerve* is the abducens; it is a motor nerve, and supplies the external rectus muscle of the eye. The *eleventh cranial nerve* is the spinal accessory; it is a motor nerve and supplies the trapezius and sternomastoid muscles.

4. *Four divisions of the circulatory system:* Heart, arteries, capillaries, and veins. The circulation of the blood is regulated in (a) *the arteries* by: (1) The elasticity and tone of the arteries, (2) the force and frequency of the cardiac contractions, (3) the resistance in the capillaries; (b) in the *capillaries* it is regulated by (1) the action of the heart, (2) the action of the arteries; (c) in the *veins* it is regulated by (1) the action of the heart, (2) aspiration of the thorax, (3) the contraction of the muscles, and (4) slightly by the valves in the veins.

5. Lymph is a colorless, albuminous fluid, alkaline in reaction, with specific gravity of about 1015, containing lymph corpuscles, and coagulating when drawn from its vessels. *Composition:* Proteins (serum albumin, fibrinogen), sugar, sodium chloride and carbonate, water, urea.

Chyle looks much the same, but has a milky appearance owing to the presence of fats.

6. The second sound of the heart is caused by the vibration due to the closure of the semilunar valve; coincident with it are: the commencing dilatation of the ventricles, opening of the auriculo-ventricular valve, continuation of the auricular diastole, and closing of the semilunar valves.

The second sound is heard best over the second right costal cartilage.

7. During contraction the following changes take place in a muscle: (1) It becomes shorter and thicker, but the volume remains the same. (2) It consumes oxygen. (3) It sets free carbon dioxide. (4) It forms sarcolactic acid. (5) It becomes acid in reaction. (6) It becomes more extensible and less elastic. (7) There is an increase in heat production, and consequently a rise of temperature. (8) The electrical reaction becomes relatively negative.

8. *The functions of the spinal cord* are: (1) The con-

duction of nerve impulses; (2) reflex action; (3) coordination; it also contains special centers which preside over definite functions.

The special centers in the spinal cord are: the cilio-spinal, secretory, vasomotor, genital, vesical, and rectal centers.

BACTERIOLOGY AND HISTOLOGY.

1. *Bacteria* are unicellular organisms of vegetable nature, devoid of chlorophyl, and multiplying by fission. They are recognized by their shape, size, motility, grouping, growth, and behavior to cultures and staining reagents. The chief culture media are: milk, blood serum, bouillon, gelatin, agar, potato. The conditions favorable for their growth are: moisture, temperature of between 10° and 40° C., nutritive material in the shape of decomposable organic matter, a medium of neutral or faintly alkaline reaction, rest, and absence of bright light; most of them require oxygen. Variations of these requirements are found. Bacteria enter the body through the abraided skin or mucous membrane, or through the alimentary, respiratory, or genito-urinary tracts.

2. *Pyogenic* bacteria are such as produce pus.

Important pathogenic anaerobes: Tetanus bacillus, bacillus of malignant edema, and bacillus of symptomatic anthrax.

3. *Germicides* are agents which destroy bacteria and their products.

Antiseptics are agents which prevent or restrain putrefaction.

Asepsis is absence of bacteria and their products.

Sterile denotes that a substance is free from live bacteria.

Disinfectant is an agent which restrains infectious diseases by destroying or removing the specific poisons which cause such diseases.

Spore is a tiny body which, under certain conditions, appears in bacteria and enables them to continue their existence under unfavorable conditions.

Flagellum is a delicate filament attached to bacteria, and is supposed to aid in locomotion.

Mycelium is a mass of interlacing filaments or hyphæ found in fungi.

4. *Fluid culture media* may be sterilized by heat or filtration; *test-tubes*, by dry heat; *rubber gloves*, by dry heat; *rubber stoppers*, by immersion for one hour in a 1:1000 solution of mercuric chloride; *cotton plugs*, by hot air.

5. The *gonococcus* is usually found in the male urethra, the female genital tract, and the conjunctiva. It appears in the form of diplococci; is biscuit-shaped, non-motile, non-sporogenous, aerobic, parasitic, without flagella, stains readily with the basic anilin dyes, and is Gram-negative.

To demonstrate *gonococci:* On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismark brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes*, which have been *decolorized by Gram's stain*, and have taken the counterstain.

6. *Fibrous tissue* "is a kind of connective tissue in which the white fibres predominate; it is found in tendons and ligaments, in the periosteum, dura mater, true skin, the sclerotic coat of the eye, and in the thicker fasciæ and aponeuroses of muscle.

The tissue is one of great strength; this is conferred upon it by the arrangement of the fibres, the bundles of which run parallel, union here, as elsewhere, giving strength. The cells in tendons are forced to take up a similar orderly arrangement, and are arranged in long chains in the ground-substance separating the bundles of fibres, and are more or less regularly quadrilateral with large round nuclei containing nucleoli, which are generally placed so as to be nearly contiguous in two cells. The cell spaces in which the cells lie are in arrangement like the cells; they can be brought into relief by staining with silver nitrate."

Elastic tissue "is a form of connective tissue in which the yellow or elastic fibres predominate. The yellow fibres are larger than those found in areolar tissue, and are bound into bundles by areolar tissue. It is found in the ligamentum nuchæ of the ox, horse, and many other animals; in the ligamenta subflava of man; in the arteries and veins, constituting the fenestrated coat of Henle; in the lungs and trachea; in the stylohyoid, thyrohyoid, and cricothyroid ligaments; and in the true vocal cords. Elastic tissue being extensible and elastic (*i.e.* recoiling after it has been stretched), has a most important use in assisting muscular tissue in a mechanical way, and so lessening the wear and tear of such an important tissue as muscle. Thus, in the ligamenta subflava of the human vertebral column it assists in the maintenance of the erect posture; in the ligamentum nuchæ in the neck of quadrupeds it assists in the raising of the head and in keeping it in that position. In the arterial walls, and in the air tubes and lungs, it has a similar important action." (Halliburton's *Physiology*).

7. *Neurone* is a nerve cell with all its processes.

Dendrite is a process of the nerve cell which brings impulses to that cell.

Axone is a process of the nerve cell which carries impulses away from the cell.

Implantation cone is a small elevation sometimes found at the junction of the axone and cell body.

Axis cylinder is the same as the axone.

8. *Peyer's patches* are aggregations of solitary glands, measuring from about half an inch to three inches in length; they are found mainly in the ileum, but also occur in the duodenum, and jejunum; they are situated lengthwise in the intestine, and are located opposite to the mesenteric attachment. Each patch is surrounded by a group of the crypts of Lieberkühn. There are said to be from 30 to 50 of these patches in the human intestine. As a rule, they have no villi on their surface.

9. *Structures found in the portal canals of the liver* are: Artery, bile duct, vein, lymphatics, and connective tissue.

10. *The stages of caryokinesis* are: (1) The *prophase*, or stage of preparation of the nucleus for division; (2) the *metaphase*, or separation of the nuclear constituents; (3) the *anaphase*, or formation of two daughter nuclei; (4) the *telophase*, or reconstruction of the two daughter nuclei, and the division of the cytoplasm.

Formation of the achromatic spindle: This occurs during the prophase. The centrosome divides into two daughter centrosomes; each of these is surrounded by its attraction sphere; the two centrosomes move apart but remain connected by fibrils; these fibrils form the achromatic spindle.

MATERIA MEDICA AND THERAPEUTICS.

1. IODIDES. *Therapeutic use:* "Iodides are believed to be more or less specific in tertiary syphilis and actinomycosis. *Iodides* are also employed in: (1) The asthma of emphysema and chronic bronchitis. (2) Arteriosclerosis and some other conditions with chronic connective-tissue production; not in cirrhosis of the liver or chronic nephritis (unless for arterial hypertension). (3) Aneurysm of the aorta. (4) Cases with high arterial tension, from whatever cause. (5) Chronic rheumatism or rheumatoid affections. (6) Poisoning by the heavy metals. (7) Colloid goiter. It is generally thought that they should not be used in hyperthroidism.

Contraindications.—The chief of these is pulmonary tuberculosis. (From Bastedo's *Materia Medica*, etc.).

2. THREE DRUGS USED TO RETARD THE HEART'S ACTION. (1) *Aconite*, dose 10 minims of the tincture. It is supposed to stimulate the vagus nerve; the diastole is prolonged, and the heart is slowed. (2) *Veratrum*, dose, 20 minims of the tincture. It is supposed to stimulate the vagus nerve, and slow the heart. (3) The *nitrites*, dose of amyl nitrite, 2 to 5 minims, by inhalation. The nitrites act by dilating the arterioles; this may happen from the action of the drug on the ends of the nerves, and also on the arterial muscles (chiefly the latter).

Three drugs that increase the heart's action: Digitalis, epinephrin, and pituitrin.

3. *Medicinal procedures in a case of eclampsia with*

convulsions: "The principal reliance for controlling the convulsions is on the combined use of ether-oxygen inhalation, veratrum viride, or nitroglycerin, catharsis, diaphoresis, active diuresis by hypodermoclysis (and the prompt evacuation of the uterus). For veratrum, chloral may sometimes be substituted." (Polak's *Manual of Obstetrics*).

4. ℞. Apomorphinæ hydrochloridi..gr.ss
Strychninæ sulphatis.....gr.ss
Heroinæ hydrochloridi.....gr.j
Spiritus chloroformi.....ʒj
Aquæ q.s. ad.....ʒij Misce
Signa: One teaspoonful q.3.h.

5. As a general rule, ether would be the anesthetic of choice. But chloroform may be used: (1) In hot climates; (2) when large numbers of persons have to be rapidly anesthetized; (3) in brain surgery; (4) in labor; (5) in patients who are known to take ether badly; and (6) in the conditions mentioned below, in which ether is contraindicated. The following *contraindications* for ether and chloroform are from Hare's "Practical Therapeutics": "*Ether* should not be used by inhalation in bronchitis or acute nephritis because of its irritant properties; in peritonitis or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible. *Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

6. *Three vasomotor depressants:* Amyl nitrite, 3 minims; spirit of glonoin, 1 minim; sodium nitrite, 1 grain.

Three vasomotor stimulants: Citrated caffeine, 5 grains; extract of ergot, 4 grains; adrenalin chloride, 1/150 grain.

Three mineral cathartics: Mercury with chalk, dose 5 grains; sodium sulphate, dose 2 drams; magnesium sulphate, dose 4 drams.

Three vegetable cathartics: Castor oil, dose 6 to 8 drams; resin of jalap, dose 2 grains; fluid extract of cascara sagrada, dose 15 minims.

7. *Diarrhea in children:* Fresh air, preferably in the country, or at the seashore, is advisable; bathing is of advantage. Food must not be given, but thirst may be controlled by water, or albumin water. Buttermilk, given two or three times a day, has been recommended. The alimentary tract must be cleared out; calomel and sodium bicarbonate will accomplish this for the small intestine, and irrigation is best for the colon; after the digestive tract has been cleared out, spirit of chloroform may be given for the pain. If vomiting is present, an emetic should be given, or the stomach should be washed out.

8. *In blood transfusion:* "The donor should be a healthy adult, with a negative Wassermann reaction. His serum should not agglutinate the corpuscles of the patient, and the patient's serum should not agglutinate the donor's corpuscles. Agglutinins should be excluded by tests done immediately before the transfusion and a single examination is not sufficient to establish the compatibility of two bloods on all future occasions. If agglutinins are absent hemolysis will also be absent. If there is great urgency, and testing of the blood of patient and donor are impracticable, a small preliminary transfusion should be done half an hour before the main mass of blood is transfused, so that gross incompatibility may be recognized in time. Febrile reactions occur after about 25 per cent. of transfusions, even though the bloods of donor and patient have been shown to be compatible. Rigors occur in about 10 per cent. of the cases." (From Da Costa's *Modern Surgery*).

9. *Phagocytosis* is the phenomenon of various ameboid cells by which bacteria and other particles of matter are engulfed or absorbed by these cells.

Leucocytosis is an increase of the number of colorless corpuscles of the blood.

Emmenagogue is an agent which induces the menstrual flow.

Hydragogue is a cathartic which produces copious watery stools.

10. *Treatment of croup.* First, be sure that the case is not one of diphtheria.

"During the paroxysm, the child should at once be placed in a hot bath and hot or cold compresses should be applied to the throat. These measures should be preceded or followed by the administration of a mild emetic. The syrup or wine of ipecac, in doses of ʒss to ʒi every few minutes until vomiting is produced, is very efficient. Bartholow recommends turpeth mineral, gr. i to iii; Da Costa suggests the cautious use of apomorphine hydrochloride, gr. 1/10. In very severe paroxysms the inhalation of chloroform may be necessary.

As soon as the paroxysm has been broken a laxative should be given. Calomel, gr. ii and sodium bicarbonate, gr. iii, should be administered and followed in six or eight hours by a dose of castor oil or magnesia. During the intervals between the paroxysms, small doses (♏v to x) of the syrup or wine of ipecac, or the following should be given:

℞. Tincturæ aconiti.....♏xxiv
Syr. ipecacuanhæ.....fʒiss
Tincturæ opii camphorat.....fʒiij
Liquor. potassii citratis. ad....fʒiij
M. S.—One teaspoonful every hour or two.
(From Hughes' *Practice of Medicine*).

CHEMISTRY AND TOXICOLOGY.

1. *Symptoms of acute phosphorus poisoning:* "Eructation of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours pain in the throat, a sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody, and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually about the fourth day the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies."—(From Witthaus' *Essentials of Chemistry and Toxicology.*)

Treatment: By an emetic or the stomach tube remove from the stomach all of the poison which has not been absorbed; then give old French oil of turpentine or potassium permanganate; the food must be free from fats and oils.

Test for phosphorus: "Mitscherlich's process for detecting phosphorus is based upon the property of unoxidized phosphorus of becoming luminous in the dark. The matters supposed to contain the poison are rendered fluid by dilution with water, and acidulated with sulphuric acid. They are placed in a flask upon a sand bath, and the flask connected with a Liebig's condenser, which is placed in absolute darkness. Upon heating the flask any phosphorus present is volatilized, and, condensing in the tube, forms a luminous ring. This reaction is very delicate, and the appearance of the ring is proof positive of the presence of unoxidized phosphorus."—(Witthaus' *Essentials of Chemistry and Toxicology.*)

2. *Wood alcohol* is methyl alcohol; it differs from grain alcohol (which is ethyl alcohol) in specific gravity, boiling point, and in its oxidation products. The oxidation products of methyl alcohol are formaldehyde and formic acid; the oxidation products of ethyl alcohol are acetic aldehyde and acetic acid. Further, methyl alcohol is exceedingly injurious. Methyl alcohol has the formula $H.CH_2OH$; ethyl alcohol, CH_3CH_2OH.

Symptoms of poisoning by wood alcohol: "Gastrointestinal disturbance, abdominal pain, general weakness, nausea, vomiting, vertigo, headache. The symptoms of ordinary alcoholic intoxication supervene, with

delirium, restlessness, unconsciousness, collapse, and coma. The pupils are usually dilated and irresponsive; nystagmus may be present. Dyspnea and cyanosis are marked. The temperature is subnormal. There is optic injury, the symptoms of which are bilateral, and consist in scotoma, dimness, or total blindness, the pupils are dilated and insensible to light. The loss of vision may start in a few hours, or be delayed several days; it generally becomes complete; subsequently there is some improvement, which in most cases finally relapses into total blindness."—(From Sollmann's *Pharmacology.*)

Treatment of poisoning by wood alcohol: Wash out the stomach, and administer a hypodermic of pilocarpine; strychnine is a serviceable tonic, and the iodides are said to benefit the amaurosis. Rectal injections of normal saline solution are useful.

3. *Two remedies which have been recommended for use in cases of chronic lead poisoning are:* (1) Potassium iodide, which is said to increase the elimination of the lead, and (2) magnesium sulphate, which converts the lead in the alimentary tract into lead sulphate (which is said to be insoluble). The value of these "remedies" is doubtful.

4. $Hg_2Cl_2 + 2KI = 2KCl + Hg_2I_2$.

Mercurous iodide is a greenish-yellow, amorphous powder, insoluble in water and in alcohol.

5. *Anhydrous* denotes the absence of water, especially water of crystallization.

Deliquescent substance is one which absorbs moisture from the air.

Efflorescent substance is one which, on exposure to air, loses its water of crystallization.

6. In *tetanus*, the onset is gradual, is apt to begin with trismus, swallowing is difficult or impossible, the condition is persistent, consciousness is dulled or lost, and there is history of a wound or injury. In *strychnine poisoning* the onset is more sudden, the muscles of the jaw and neck are generally the last to be affected, there are marked remissions with muscular relaxation, consciousness is retained, and there is no history of a wound or injury.

7. *Test for lactic acid in stomach contents:* Mix equal parts of Uffelmann's reagent and filtered stomach contents; the blue color is changed to a canary yellow by the presence of lactic acid.

8. *Test for blood in urine:* Boil a small amount of the urine in a test tube, add caustic soda and continue to boil; the phosphates and coloring matter of the blood precipitate showing a brownish-red color, while the supernatant fluid is of a bottle-green color.

9. Uric acid is a dibasic acid, with the formula $C_5H_4N_4O_3$. It belongs chemically to the group of substances called "purins," uric acid being trioxypurin. The uric acid which is derived from the purin bodies contained in the food is called "exogenous" uric acid; while that which comes from the breaking down of the tissues of the body which contain amino purins and oxypurins or nucleins is called "endogenous" uric acid.

Test for uric acid: Add a little dilute nitric acid, evaporate nearly to dryness, cool, add a little ammonium hydroxide. If uric acid is present the nitric acid residue is yellowish-red, and on the addition of the ammonium hydroxide a reddish-violet color is produced.

10. *Enzymes* are organized ferments produced by living cells; they cause definite chemical changes in certain substances. They are soluble in water, in glycerol, and in dilute salt solution; they are precipitated by alcohol and by ether; they work best in a temperature of about 40° C., but there are exceptions, each enzyme having its own optimum temperature; each enzyme has a very limited action, being specific for one substance only; each enzyme will work only in a medium of definite reaction, either alkaline or acid; and the products of their activity must be removed. When these conditions are fulfilled, enzymes are capable of doing a large amount of work.

(*To be continued.*)

Sequelæ of Epidemic Encephalitis.—Remond and Lannelongue report five cases of the disease and emphasize the frequent and often severe relapses and further the exhaustion syndrome which may follow the malady. The latter may suggest that the patient has developed multiple sclerosis.—*La Presse Médicale.*

Therapeutic Hints.

Neuritis Due to Autointoxication.—G. N. Murphy, after suffering for nine months from neuritis, which failed to yield to various methods of treatment, prescribed by himself or other physicians, concluded that his trouble was due to autointoxication. He then formulated the following prescription:

Creosote	drs. 2
Soluble iodine	drs. 2
Turpentine	dr. 1
Oil of cloves	dr. 1
Menthol	grs. 10
American oil	oz. 16

Mix well by shaking and take one tablespoonful twice a day—night and morning.

This was followed, the first week, with a saline flush of the bowels each morning; after that, and during the remainder of the treatment, he flushed the bowels every alternate day. He also largely eliminated from the diet such articles as lean meat, eggs, cheese, rich pastries, pickles and highly seasoned articles, and drank about two quarts of water every twenty-four hours. Under this plan of treatment he made a good recovery.—*Clinical Medicine.*

Habitual Vomiting in Young Infants.—Marfan, holding that the treatment, at first, is the same whether the physician is confronted with habitual vomiting or with pyloric stenosis, the differential diagnosis often being impossible until after a certain period of time, says certain external remedies and some medicines must be employed along with the regimen of feeding. In the common form of habitual vomiting the treatment is limited to the employment of enemas of very hot water (104° to 105° F.), and the administration of certain antidyspeptic medicine, among which the subnitrate of bismuth occupies first rank. The following prescription is recommended:

℞ Subnitrate of bismuth ..... gr. 2
Sweetened mucilage,
Syrup ..... āā mils. 45
Shake.

Sig.: One coffeespoonful, five to ten minutes before feeding, six times daily, or, then, four times a day, ¼ gram of subnitrate of bismuth given with the bottle.

If it is suspected that hyperacidity contributes to maintaining the vomiting, one may give, one hour after feeding, an alkaline substance (bicarbonate of sodium, citrate of sodium, lime water). Gastric ferments, such as rennet, have been advised and pepsin and papaine have been recommended.—*Clinical Medicine.*

Constipation in Old People.—A. J. Reppito recommends the following for old people, as it acts on the urinary as well as the digestive system:

℞ Fld. ext. cascara .....
Fld. ext. queen of the meadow ....
Fld. ext. parsley root .....
Tinc. senna .....
Glycerin .....
Water ..... āā, ℥j

M. Sig.: One teaspoonful in water three or four times a day, governing dosage by action.—*Medical World.*

THE INFLUENCE OF RADIOACTIVITY IN THE TREATMENT OF HYPERTENSION.*

BY C. EVERETT FIELD, M. D.

NEW YORK.

DIRECTOR OF THE RADIUM INSTITUTE.

THE kind invitation of your presiding officer for me to address your worthy society also included the subject of the desired talk, therefore I have no option. While it is of utmost importance for us to study measures of prevention and control of symptomatic high blood pressure, and to employ our time in an effort to gain better results in the polyarthritis case, still somehow my heart clings to that employment of radium which gives relief and hope to the greatest sufferer we know—the patient afflicted with malignant disease. It is in that climax of suffering, we meet that which encourages us most. Radium, here, frequently by its power to control hemorrhage, allay pain, check odor, exerts a tonic influence that puts even a forlorn hope in the mind of the hopeless.

It is possible, therefore, that I would have preferred to tell you something of this phase of my work, but sometimes it is just as important to help the class of patients we are now to consider, to abate their distress, increase their span of life, and aid them to "grow old gracefully."

The theme of symptomatic high blood pressure, hypertension, or arteriosclerosis, as you may elect, forms an enormously important subject for discussion, not so much on account of the early classic symptoms by which we recognize the abnormality, but because we now classify it as the forerunner of most serious degenerative changes in the cardiovascular, renal, and cerebral systems.

Our attention, as physicians, is keenly directed to the rapid increase in mortality statistics of those just past 45 and 50 from diseases of the kidney, heart, and circulatory system. We are intent in our study of such measures of diet and hygiene as might increase the life period of this class of patients. They represent those of active intellectual pursuit and those of sedentary occupation. Rarely do we meet hypertension in the man who toils with muscle and brawn.

It is my firm belief that by an early recognition of the manifestations first recorded as hypertension and with the inauguration of measures at our command, we can prolong life for many years in at least 75 per cent of such cases.

*Read by invitation before the Flatbush Medical Society, March 12, 1920.

It is our duty to watch our healthiest clientele, those who pride themselves in never having a day of sickness, who may, however, acknowledge slight tendency to gastric or intestinal fermentation of excessive type. Such should be educated to the possibilities and taught the importance of a periodic routine examination.

With the patient, however, referred to us with the clear evidence of head symptoms, precordial distress, a possible nephritis, and high blood pressure, our picture is changed and we are called upon to give relief. We have little use for the one-remedy man, any more than we would favor one sectarian religious creed for the moral ills of the whole world.

Treatments that may avail cover diet, baths, mineral waters, electricity, thermal applications, measures of regime and hygiene, stimulant drugs, ferment bacilli, and a long list of therapeutic hints not to be mentioned.

During the past five years we have been giving our attention to radium, following the rather exaggerated reports of success coming from the European Spas.

Observing carefully our clinical results, together with conservative deductions made from our laboratory findings, we do not hesitate in placing radium in the very forefront of therapeutic measures for the relief of hypertension. The liberal colleague will of course understand that we advance radium therapy only as an adjunct to such system of treatment as seems indicated. Furthermore, owing to the scarcity of radium, and the expense entailed, it should naturally be called in service only when other treatments fail to bring the full relief desired or fail to hold that relief with a degree of permanency.

If we are true in our personal estimate of the virtue of radium, it will in turn interest you, the general profession, to know more intimately its physiochemical properties, following internal administration.

In presenting the cause of radium, as a measure of treatment in symptomatic hypertension, let us keep in mind the fact that we are considering the use of a physical agent, rather than a drug. We will gain a better conception of the modus operandi of its physiochemical influence if we recognize in radium a means, as described by von Noorden, of introducing into the tissues, cell structures, and protoplasm of the body, a current of fluid electricity.

Hypertension in periods long or short, precedes degenerative processes, and at times gives but little warning, owing to the promptness with which some form of compensation takes place. We may also

conclude that hypertension from any cause cannot persist for any considerable period without developing organic changes in the heart, kidneys, and general vascular system.

In a brief consideration of etiology, we will simply refer to the predisposing and direct causes such as overwork, loss of sleep, nerve strain, faulty digestion, and toxic principles. Romberg is quoted as saying, "Everyone acquires his arteriosclerosis within the circuit which he has taxed most." Metabolism is the copestone of hypertension. Finding all channels leading to the exhibition of toxic influence, we naturally cast our hope for a lifting of the veil on the biochemist. Recognizing, then, fully the status of the body ferments and the fact that each acts in harmony with constituents of its own substance, we can readily see how complex must be a study of the multitude of ferments, which in the body combine to build up all that is vital and to consume that which is waste.

The administration of drugs with the hope of influencing metabolism, we can readily appreciate, fails, owing to the complex balance in which the various ferments are sustained. The metabolic deficiency may be sought for in some of the toxic conditions dependent upon the ductless glands.

The theories relating to the causative features of high blood pressure are many; but for our immediate need we care not to debate now whether it is due to a hyperplasia of the suprarenal capsule, or, according to the old theories of Cohnheim and Traube, to mechanical interference in the flow of the blood stream, for we may content ourselves in the belief as clinicians that faulty ferments of toxic origin are the basic factors.

To have the radium situation clearly before our minds, we must acknowledge that much of the early experimental research with radium had many of the hindrances common to the study of so rare and new an element.

From the earliest experiments to the present, lowering of high blood pressure during radium treatments has been the common report. Physiochemical processes are exact and the physiological and biological manifestations that follow must to a similar degree, be definite. Therefore it is that, in almost 95 per cent. of the high blood pressure cases treated, certain improvements are promptly noted; precordial distress, headache, vertigo disappear at times even with small dosage. The general energy of the heart is markedly improved and peripheral resistance is reduced. A factor that by some has been discounted is the viscosity of the blood, yet a change in type exerts an enormous influence of the arterial system; under emanation it is rendered less viscid. The elasticity of the muscular wall of the artery relieves the heart of much unnecessary load. When the tonicity is low, increased tension results. Radium emanation improves the general muscle tone of the entire system.

Recently, Dr. Sailer said: "The fundamental element in physics, in chemistry, possibly in the universe, was the atom, and until a clear idea of the structure of the atom was had, much progress in the solution of the problems under consideration could not be made." The close inter-relation of ionization and colloidal states is vital in our study of every phase of the high blood pressure subject.

The phenomena of ionization as evidenced in many of the normal ferment processes may be illustrated in its importance by a definition: "The modification of a substance by which it acquires electrical charges is termed ionization; for instance, common salt and sugar in water, designated formerly as a solution. We now know that the activity of the salt is materially increased while the sugar suffers no change—the sodium atoms acquiring a positive electrical charge and the chlorine atoms a negative charge." The above thought by Leffman is here introduced with the hope of paralleling the action of radioactivity in activating chemical processes, and at the same time to give appreciation of his work.

According to von Noorden, redioactive elements exert forces which, in accord with the definite laws of physics, markedly influence biological processes. Furthermore, the chemicophysical properties of radium may be traced in the human body even in the minutest doses. Metabolism, while classed as a body chemistry, is in itself dependent to no small extent on physics. In the laboratory radium readily activates and intensifies fermentative and digestive processes; within the body, it stimulates even more actively the numerous ferments.

Radioactive substances present three distinct products of disintegration which we term rays. Alpha rays are positively charged helium atoms and constitute 90 per cent. of the energy of radium. Beta rays, also electrons, in turn are negatively charged particles. Gamma rays are not material in nature, being classified as exceedingly short-length waves of ultra violet light.

In the process of decay or transmutation, something happens within the tiny atom of radium, and much as the meteor flies from the planet, the alpha ray is spontaneously thrown off into space with a speed of over 12,000 miles per second. From this, another and still another particle is born until the entire series in evolution is complete. In common with the liberation of the alpha particle, we have the formation of a gaseous substance known as emanation, which contains in itself all of the power and energy of radium. The radiations of emanation acting as carriers of enormous energy within the body develop heat and electricity and foster chemical transformation. By its use we permeate the body with a stream of electrons through the channel of the blood stream. It carries a normalizing activity to the tissues, fluids, protoplasm, cells, and nuclei.

Abundant literature detailing the exhaustive biological and physiological research of worthy observers is at hand and can largely be accepted, especially that which pertains to metabolism. The careful and accurate findings of such workers as von Norden, Gudzent, His, Deutelmoser, Klemperer, Falta, and von Neusser tend to substantiate much of the true physiological effects of emanation.

The physiological manifestations of radium naturally center around its effect on metabolism and the blood. There are evidences of a selective influence as regards radium, such as the affinity that attracts it to the bone marrow, where it serves to increase markedly the red blood count. There is temporary leucocytosis. It is said to aid in

keeping uric acid in a soluble form and to promote the elimination of that already deposited. Dilatation of the blood vessels follows an excitation of the vasomotor nerves; the viscosity of the blood is diminished. Digestive processes are greatly improved by activating the ferments. Diuresis is produced. Emanation exerts stimulant, tonic, and sedative influences. Following its use respiration is improved.

The researches of Gudzent and Lowenthal in purin metabolism found it activated by the smallest doses of radioactive waters. Carbohydrates are mobilized and oxidized in increased quantities. Bickell and Bergell have proven the activation by emanation of peptic ferments in the stomach. Braunstein, Richet, and Deutelmoser also have reported as to the activities of glycolytic, urolytic, pancreatic, and lactic-acid ferments. Neuberg has given valuable data on autolytic fermentation.

That radium increases protein metabolism indicates its use in gout and old age conditions. There remains a mass of work already reported as to metabolic activation with radium which we cannot even here mention; we, however, must let these brief references be left as indicative, and hasten on to the more recent work with radium therapy that bears directly on our subject.

Quite recently (1917 Zwaardemaker, physiologist at the University of Utrecht, made the startling statement that radioactivity possesses a significant, if not the essential force in controlling the automatic action of the heart. This belief has been more or less common among many radium therapists during the past ten years. He shows that of the twelve elements which go to make up the animal tissues, two possess characteristic atomic property which may enable them to exert unusual influences. Iron is ferromagnetic and potassium is reputed to be radioactive. Although the emanation activity is very low, it may serve to hasten other chemical forces.

Negatively charged beta particles of radium produce coagulation of oppositely charged colloids and the effect appears to be an electrical one. Potassium gives off beta rays of high penetrating power, but that they are few in number is shown by the fact that it takes over fifty days to appreciably fog a photographic plate. Its ionizing power is a thousand times weaker than that of uranium.

Zwaardemaker's experiments covered the excision of a heart and causing it automatically to keep beating by perfusing suitable chemical circulating fluids. He found that when potassium was omitted from the fluid the heart immediately ceased beating. By renewing the potassium the automaticity was assured. He then found that he could substitute radioactive substances other than potassium, using equiradioactive quantities of thorium, uranium, or rubidium, and that they were equally effective.

Presuming then that such substitution proved that radioactivity in some forms was a necessary adjunct to the circulating fluid, he describes radioactivity as one of the essential factors in the automatic function of the heart. My only reference to the value of this experiment is to direct attention to the possible value of even minute doses of radium, and further, that suitable dosage might be estimated to make up the required energy when potassium is deficient or lacking.

I am frequently asked the question, "Just what can we hope for clinically?" Recognized early, metabolic deficiencies may be promptly improved with the hope of a permanent cure. We have a right to assume that the process of hypertension can be checked so as to prevent the development of a nephritis. When nephritis and cardiac lesions are advanced, the pathological processes can surely be held in check and life in a measure conserved; while at the last stake with a broken compensation we may sustain the patient by lowering tension, building up resistance, increasing somewhat the elasticity of the blood vessels, thereby lessening the danger of their rupture and materially adding to the comfort of the patient.

Administration.—Radium may be administered by means of emanation inhalation, radioactive waters for drinking, solutions of radium salts for drinking, by means of emanation baths, or by intravenous or subcutaneous administration of radium bromide or radium chloride. Wherever dosage in micrograms of radium salts is quoted, it refers to *radium element.* Radium has absolutely no toxic effects, it being accepted as harmoniously by the human system as is sunlight by the plant.

The classification of clinical and dosage data reported by Rowntree and Baetjer is of considerable worth. Dosage in radioactive or emanation water is being used in variation of from 1,000 to 1,000,000 Mache units, and the pure radium element in the form of radium chloride has been administered intravenously in dosage as high as 1,000 micrograms or the equivalent of 2,700,000 Mache units in one dose without any untoward effects. With radioactive waters, van Noorden found but little result until his dosage of water approximated 20,000 Mache units daily. The usual dose of radioactive or emanation water used by the London Radium Institute gives a minimum of 250,000 Mache units daily and a maximum of 1,000,000 Mache units. Proescher and Cameron have made over 2,000 intravenous injections of radium chloride in doses averaging 50 micrograms, and my personal observations cover the administration of over 2,800 similar treatments, and I find no report of any unpleasant effects. The radium is not permanently deposited, and that it is finally eliminated from the system is well covered in a research by Seil, Viol, and Gordon, who showed the character of complete elimination and its duration in the human.

Most interesting research is now being made in measuring the radioactive content of the blood for weeks following treatment. The activity of radioactive waters is of short duration and consequently they are limited in their application. It is probable that no emanation can be traced two hours after taking, whereas radium solution by mouth can be traced and measured up to the sixth day. Following an intravenous injection of radium chloride, it can be traced in the blood at least twelve weeks thereafter. Subcutaneous application of the radium by injection reduces its dosage effect about one-half. Some of the earliest of injections of radium element were made by Brill, Falta, Freund, Zehner, and von Noorden.

So far as dosage is concerned in high blood

pressure, we are largely governed by the chronicity of the case and the involvement. Personally, I feel my best results have been shown in what we would term low dosage. Delano of Boston has checked up some exceedingly important findings derived with low dosage. He has found his average dose to be 4 micrograms daily.

It is my usual plan to give an injection of one 25 micrograms (radium chloride) ampulle (2 c.c. normal saline solution), and following with a solution of distilled water, 2 oz., containing 2 micrograms of radium chloride given by mouth as one dose three times a week. After four weeks this drinking solution is cut to two doses per week. While the results are prompt, I never accept a case for less than twelve to sixteen weeks treatment and observation. Careful record of the laboratory findings are always to be made.

The patient may or may not be placed on diet and other rules of hygiene as may seem indicated. In private cases I would of course observe the above, in others I have preferred to watch the results without special or rigid diet. Under such a treatment we have a right to expect by far the large majority of cases of systolic pressures (running from 160 to 200mm) to be influenced to drop from 15 to 40mm. As a rule, active symptoms such as precordial distress, vertigo, and headache disappear in many cases within a few days.

Where radium solutions by mouth alone are given, my dosage starts at 6 micrograms per day in three doses; this to continue for four weeks as a rule, then to follow at 6 micrograms per week for the balance of the course. This plan of treatment does not give as uniformly good results as a course inaugurated with an intravenous injection. The plan of insisting on the long time treatment was arrived at, owing to the fact that after the initial drop in pressure, or within five days, the patients generally felt so much improved that there was a tendency to discontinue treatment. It was necessary to make it clear that the early relief had nothing to do with the permanency of the effect most to be desired. Patience and real radium with or without a portion of psychology are necessary factors to the successful administration of those cases. In your mind will naturally arise the question, what of the permanency of such treatment?

To this I can reply that fully three-fourths of the cases have held without further treatment for from six to twelve months. There are many of the early cases treated nearly four years ago that have suffered no material rise. Others where pressure has gone up sufficiently to produce symptoms have been quickly touched up with a two or three weeks treatment. Some of these returned with their trouble on account of growing bold with their diet. An interesting feature in a large number of my cases has been an activation of sexual powers. Insomnia and nervous symptoms are improved and the patients invariably take on a feeling of well being.

Compensatory functions can be sustained and greatly improved at times with extremely low dosage of radium. In such cases we may observe both systolic and diastolic pressures slowly coming down in a fairly even proportion. Although I can find no record of any unfavorable action following the administration of the soluble salts of radium, I would naturally urge caution in attempting sudden reductions in compensatory high pressures. Here must come a full understanding as to the type of compensation. For the purpose of this paper I have intentionally refrained from dealing with compensatory cases and my selection has been in a measure confined to those types showing relatively a high systolic and a lower diastolic pressure.

205 W. 70TH STREET.

HYPOTHYROIDISM — TWENTY-SIX YEARS' SUPPLEMENTAL THYROID FEEDING.*

BY DANIEL B. HARDENBERGH, M.D.,

MIDDLETOWN, N. Y.

IN 1873 Sir William Gull called the attention of the medical profession to a diseased condition that he termed "cretinism" in a paper entitled "A Cretinoid State Supervening in Adult Life in Women." This was the first recognition, apparently, given to a constitutional disease that has obtained considerable attention of late. The next contribution was from Ord, who, in 1877, grouped these cases under the term "myxedema" and discussed the relation of this condition to atrophy of the thyroid gland and to a similar condition occurring in children, then termed "cretinism." This condition in children had been noted as occurring both in groups and in isolated cases, and had been further designated as "epidemic" and "sporadic cretinism." In Germany Kocher had already noted that in certain instances of total extirpation of the thyroid gland a remarkable cachexia developed termed "cachexia strumipriva." In England Horsley demonstrated experimentally that removal of the thyroid gland from the lower animals produced symptoms identical with those of myxedema and the cachexia strumipriva.

Further elucidation of the subject was made by the Clinical Society of London in 1888, whose report of the type-signs as described by Ord remains classical and deserves full enumeration.

The marked increase in the general bulk of the body, the firm swelling of the skin, not pitting on pressure, inelastic, adherent to the parts beneath and not affected by gravitation; the dryness and roughness of the skin, tending with the swelling to obliterate all lines of expression; the imperfect nutrition of the hairs, leading to their loss; the local tumefaction of the skin and subcutaneous tissue noticed in various parts of the body but most frequently in the sub-clavicular regions; the turgesence and infiltration of the mucous membranes, leading in the mouth to an affection of the teeth homologous with that of the hairs just mentioned; the remarkable physiognomy; the slow, painful utterance, monotonous voice and leathery quality of tone thereof with curious nasal explosions at short intervals during speaking; the slowness of thought and movement; the slowness of perception and response; the defect of memory; the frequent occurrence of mental disorders of an irritable and suspicious character or of hebetude and somnolence, alternating with excitability; the tendency to fall owing to disorder of coordination; the existence of subnormal temperature of the body; the aggravation of all symptoms during low climatic temperatures, and the diminution or apparent absence of the thyroid gland. Among the minor or accessory signs may be noted abnormal subjective sensations belonging particularly to taste and smell, oc-

*Read before the First District Branch of the Medical Society of the State of New York, October 21, 1920, Poughkeepsie, N. Y.

cipital headaches, marked alterations of temper and a curious persistence of thought and action, overriding all attempts at interruptions by friends or observers.

The above is the description of a condition resembling in single symptoms a number of other diseases but in its entirety clean-cut and striking.

In regard to frequency in its fully developed state it is no doubt and very fortunately rare but not so rare I believe as has been considered. At a medical congress in Scotland where the subject was discussed Prof. Hoffmann remarked that in Heidelberg he hed seen only one case and from the United States Mackenzie stated that he did not believe that any case had ever been met with in Cincinnati.

We must remember however that until recently little encouragement had been extended for the recognition of this condition as the treatment was practically hopeless. While from a scientific standpoint it is difficult to justify the fact it no doubt is a fact that men will concern themselves much more to recognize a diseased condition when that condition is amenable to treatment than when it is not.

As usually happens, the credit of discovery in the treatment of myxedema can not be attributed to a single source. Lundie (*Edinburgh Journal*, 1893, XXXVIII, 996) recounts that Kocher, in 1883, and Bircher, in 1889, had transplanted the thyroid of lower animals to the site of the extirpated thyroid in cases where the removal of the gland had been followed by symptoms of myxedema. Horsley (*British Medical Journal*, 1890, I, 287) suggested that transplantation be employed in cases of myxedema non-operative in origin. He was led to this suggestion by the observation that in his own cases of transplantation in operative cases there had uniformly been a temporary improvement following the attempted grafting of the thyroid, even when the grafting did not prove successful. In passing it may be stated that in several instances the grafting proved a success and improvement over periods of many months followed.

G. R. Murray of Newcastle, reasoning on the observation of Victor Horsley, from the thyroid glands of sheep prepared and administered extracts hypodermatically, and made the first report of this treatment in the *British Medical Journal* in 1891. The honor of establishing treatment is, however, to be shared with Prof. Howitz of Copenhagen who, in July, 1892, before the Congress of Naturalists, held in that city, demonstrated its efficacy. For a number of months the hypodermatic administration alone was employed, then the feeding of the raw gland or of the gland rarely cooked in the form of sandwiches was attempted. Reports at first failed to recommend the method of feeding on the grounds of serious digestive disturbances being provoked, but with the improvements of administration in which glycerin extracts and the desiccated glands in tablets or capsules have supplanted the crude method, the administration by mouth, except in rare cases of marked gastric intolerance, quite supplanted hypodermatic methods.

The manner in which the absence of the thyroid gland may be compensated for by the administration of extracts from other thyroid glands leads us to infer that in the thyroid are regularly produced certain organic compounds or principles that are essential in the most far-reaching way to the human economy—the secretion and nutrition of the skin and its appendages, the waste, excretion and repair of tissue, and, probably in a secondary way, the reaction and coordination of the nervous system and the mental processes themselves.

The success of the present treatment is now quite established. In England Murray, Horsley, Bramwell, Thomson and W. Pasteur were early contributors to the subject, and in our own country we were indebted to the early reports of Kinnicutt, Starr, Putnam and Crary. It will therefore suffice to proceed to the history of the case that has furnished the subject of the present paper—a case that fortunately is such in its characteristics and response to treatment as to be taken as a type.

A. C., female, thirty-seven years of age, single. Parentage, American of English-Scotch origin. Childhood history presents nothing remarkable other than an attack of scarlet fever and enlarged tonsils up to the age of fourteen when a fullness in the neck was noticed, which made relatives apprehensive of goiter. This appearance had also been presented in patient's two sisters at the same age, but in them had passed away without further disturbance. A cousin of the patient's mother on her mother's side was known at the age of sixty to have goiter, but of this grandmother's other relatives there is no knowledge. This condition of hypertrophy of the thyroid gland lasted for one or two years and received but little attention. In the cases of the two older sisters the condition was more persistent and one of them suffered many of the other symptoms of exophthalmic goiter and was for several years under treatment. Menstruation began at this time—fourteen years of age—and has always been regular, but of one day's duration, accompanied by some pain since. From the subsidence of the swelling of the thyroid gland at the age of sixteen years up to the age of twenty-five years good health was enjoyed and after finishing her own education the patient became a teacher. In the patient's twenty-sixth year—in the spring of 1882—she noticed after rising mornings that there was pain in the limbs and at the same time began to gain weight rapidly so that in less than eight weeks she had gained ten pounds. These pains were in both joints and muscles, and the movements became slow. At times the hand, then the hand and arm, then the whole side would seem paralyzed and remain so perhaps for half an hour. The speech became slow and monotonous. It was suggested that she had dropsy and again inflammatory rheumatism, but the observation was made that the flesh did not "pit" on pressure. Three months after the attack began she was obliged to give up her occupation as a school-teacher and slowly the trouble progressed so that in the fall she was kept at home and was unable to go up or down stairs. During the whole summer she did not perspire at all but felt cold. Her hair began to fall out, and two years later was very thin so that the fleshy scalp was visible. It remained in this condition for two years and then grew in sparse, coarse and dry.

From the fall of 1882, when the patient was first seen, until May, 1894—a period of twelve years—there had been no material change in her condition, though from a determination to be more self-reliant she forced herself to walk and was able to go upstairs very slowly, taking each advance step with the left leg. Under various forms of treatment there seemed at times a slight amelioration in her condition that proved very transitory. Examination of the urine never revealed albumin. She was treated during the greater part of the twelve years under as great a variety of methods as of diagnoses. The diagnoses made are of interest as suggesting the resemblance myxedema has to other pathological conditions, and included Bright's disease, inflammatory rheumatism, Addison's disease, neurasthenia, anemia, pernicious anemia, etc. In the beginning of the trouble the patient was subject to a cough, and apprehended phthisis pulmonalis. She was told there were changes at either apex. As the supra and sub-clavicular regions are the favorite seats for the

deposit of infiltration in myxedema, the attendant physical signs may have proceeded from such a condition.

To recapitulate: *Chief Symptoms*—Pain in joints and muscles, dull headache, weakness, slowness and difficulty in movements, slowness and monotony of speech, inability to carry on mental processes, total or partial, amnesic aphasia, anorexia, marked constipation.

Physical Examination: Patient very anemic. Pulmonary signs entirely normal except dulness at either apex due to myxedematous condition of cellular tissues. Heart action slow and muffled, but accompanied with no murmurs—apex beat could not be determined by palpation but from auscultation apparently not displaced. Liver and spleen normal. General appearance as shown in photograph:—skin thick, coarse and dry—in places resembling the blotches of psoriasis—fine scales becoming detached. Perspiration entirely lacking. Hair upon scalp thin, coarse and dry. Eyebrows very thin. Infiltration of skin and subcutaneous tissue particularly marked under eyes and across bridge of nose. Drooping of the pendulous features, that is, of the lower lip and upper eyelids. In the attempt to keep the thickened eyelids from closing, the forehead became permanently wrinkled and the eyebrows arched. Mucous membranes thick and friable. Nose-bleed frequently occurred. The infiltration of tissues general throughout the body. There never was pain upon swallowing, but at times inability to swallow solid food, and ordinarily the act of deglutition was accompanied by a peculiar sound.

Infiltration of the hands varied; at times patient was unable to approximate the thumb to either the tips or bases of fingers. Expression and manner that of deep hebetude. A record of the temperature and pulse at this time was made.

		Temperature	Pulse
May 19	4 P. M.	96 degrees	69
May 20	7 P. M.	98.6 "	52
May 21	9 A. M.	96 "	56
May 21	1 P. M.	95 "	60
May 21	4 P. M.	96.4 "	58
May 21	7 P. M.	95.5 "	57

The average temperature during these three days was found to be 96.25°—more than 2 degrees below normal, and the average pulse—58 2/3 beats to the minute.

On May 22 the thyroid treatment was begun, starting with one of Burroughs and Welcome's tablets, each tablet consisting of dried and compressed thyroid and representing five grains in weight of the fresh gland. It will be noted at once that this was a very small dosage. The thyroid gland in sheep varies in weight from ten grains to one ounce, and the two lobes average rather under one ounce. On May 22 the temperature ranged from 95° to 97°, and the pulse from 53 to 60. On May 23 it ranged from 95.6° to 98.6°, and pulse from 56 to 68, and the patient began to feel feverish. On the 24th, the third day of treatment, the temperature reached 99.75° and the pulse 70. on the 25th the temperature kept between 98.5° and 99.75°—the pulse between 62 and 70. Buzzing noises began to be experienced by the patient and a feeling of soreness all over the body. On the 26th the soreness had so much increased that the patient remained all day in bed and avoided moving so far as possible. Curiously enough these same sensations had been experienced twelve years before at the onset of the trouble and had never recurred with the same severity up to this time. A difference was already noticed in the patient's manner. Her responses were much quicker and speech less slow and monotonous in tone. Her bowels acted without cathartics which had come to be an unusual occurrence, and the excretion of urine was much increased. For the next week the patient remained in bed; itching of the skin became very troublesome and desquamation in places occurred. On the fifth day of treatment dosage was increased from one to two tablets per day and kept at that amount for one month. Within a few days the pains became less severe—the temperature kept between 99.5° and 100.5°, and the pulse between 66 and 82.

On June 6, two weeks after beginning of treatment, the patient was up and about the house and there was a marked change in her appearance and manner. Her eyelids and hands were thinner—her waist measured two inches less, and her speech was much more normal in rapidity and intonation. At this time the hair began to fall out. Normal perspiration began and for the first time in twelve years the patient experienced the discomforts of hot weather. At about this time occurred periods of weakness, dizziness, feeble heart action and prostration, which, in the light of a more careful study of the dangers of this treatment, I can but look back to with alarm.

It is commonly enough understood that the treatment should be administered with caution, but the extent of the dangers, in the enthusiasm which the wonderfully specific effects of the treatment arouses, is likely to be misapprehended. Dr. G. R. Murray, the initiator of the treatment, had, in his first four cases, two terminate fatally, but both were over sixty years of age and rather feeble. John Thurson at the Medical-Chirurgical Society of Edinburgh reported a fatal case—a patient who died at the end of the third week of treatment and to whom not more than three and one-half sheep's thyroids in all had been administered. In the London *Medical Press* Foule reports a death following a violent diarrhea caused by administration of a single one-eighth of a gland dose. In a collection of forty-seven cases which I have been able to study there have been four deaths. To my mind this has been no more significant than the frequency of severe toxic symptoms in the balance of the cases. In four cases that Starr reported there were alarming manifestations in two instances—his first and third cases—the third requiring most energetic stimulation and apparently very near a fatal terminus. It is undoubtedly true that in the treatment as at first conducted there have been toxic symptoms manifested in feeble pulse, prostration and syncope, such as would not be countenanced in the exhibition of any other of our more powerful drugs.

Later in the treatment, through a failure of supply of the English tabloids, I resorted to a granular extract of our own market that was sold with dosage indicated as from five to ten grains, t. i. d.—fifteen grains of this preparation representing an average thyroid lobe. Following my first intention of employing very small dosage I used but five grains *once a day* and with this, though the treatment was in the third month, I occasioned symptoms of dizziness and weakness that made it prudent for the patient to remain in bed. This was one-third of the minimum dosage recommended! A five grain capsule every other day was found entirely ample to continue treatment.

Three months after the beginning of the treatment the patient was taking one five grain capsule once a week, and this small dosage proved entirely adequate for a period. The patent from that time began to enjoy good health, so that in the following year she was accustomed to take four mile morning walks, enjoyed society, laughed, sang and was her old self again. Her skin was soft and pliable, the wrinkles faded out, and an abundant growth of fine hair appeared on the scalp, eyebrows and extensor surfaces of the limbs. Her manner was even more changed than her appearance, and the membere of the immediate family declared that they should never have recognized her as the same per-

son had they not watched the gradual transition.

A normal amount of subcutaneous fat was gradually established, and the changes in skin and hair were complete in two years. In the years that followed the patient soon learned to adjust the dosage to her own needs. Several preparations were used with satisfactory results. In general in more recent years the frequency of doses has increased. In place of one or two tablets weekly, from three to six are now required. The patient now enjoys good health, in fact has experienced no serious illnesses. The length of the period over which this recovery has continued—twenty-six years—is the most remarkable feature of the case. It is possible that in length of period of supplemental thyroid feeding and of observation the case is unique.

THE SURGICAL ASPECTS OF PLEURISY.

By JOHN F. VAN PAING, M.D.,

CHICAGO.

FELLOW CHICAGO ACADEMY OF MEDICINE.

It is not the intention of the writer to go deeply into the etiological or pathological aspects of pleurisy in this paper, but an attempt will be made so to classify the different types from an etiological and surgical point of view as to present to those interested a working basis whereby we may meet on common ground and discuss the relative merits of the classification and therapeutic procedures I will here in outline.

There are three types of pleurisy of interest to the surgeon, and they are as follows:

1. *Acute Pleurisy with Effusion*: (*a*) Primary acute effusion, partially absorbed. (*b*) Subacute effusions continuing for a period of weeks or months, primary in onset, with no tendency to absorb. (*c*) Subacute simple effusions, secondary to inflammations or infections of the lung proper, which, if left to themselves, gradually undergo partial or complete absorption with or without organization, as in the serofibrinous plastic type. (*d*) Empyema: Acute, infective effusions, primary or secondary to infective pneumonia, pericarditis, influenza are, as shown by the late war, epidemic in nature.

2. *Chronic Pleurisy*: (*a*) Chronic pleurisy with effusion, with or without an etiological basis of infection, and which usually tends to interfere with respiration. (*b*) Chronic fibroadhesive pleurisy, consisting of organized products of effusion with the formation of connective tissue, embarrassment of respiration, retraction of the chest wall, and complications such as secondary anemia, progressive weakness, dyspnea, cough, and undermining of the general health.

3. *Miscellaneous Type*: (*a*) Hemorrhagic: (1) Secondary to nephritis, heart disease, or general anasarca. (2) The breaking down of organized granulation tissue. (3) Secondary to cancer, sarcoma, etc., of the lung or mediastinum. (4) Hydatid or other cyst formation in the lungs, pleura, or diaphragm. (*b*) Localized or encysted types simple in nature and tending to undergo absorption.

Bacteriologically there are four groups due to primary or secondary infection: (1) (*a*) *Streptococcus hemolyticus*, (*b*) *Streptococcus pyogenes*, (*c*) *Pneumococcus*. (2) Staphylococcus. (3) Tubercle bacillus. (4) Friedländer's bacillus.

Acute Types.—The *streptococcic* type is, of course, the most rapid and fatal and usually follows an infection of lung tissue or a general infective bronchopneumonia. The temperature rises very rapidly, the pulse is very rapid and weak, and shock and collapse are early symptoms. The mortality in this type is extremely high and treatment in some instances seems to be of no avail. Personally, I am of opinion that this high mortality has been largely due to the fact that the patients have been treated as test-tubes and not as human beings. I further believe that exposure has taken its toll, and by this I do not mean that a patient should not have fresh air, but conservatism should be used in the "fresh air cure," especially in those debilitated individuals who fail so rapidly and who seem to have no chance from the onset.

2. Infections Due to the *Pneumococcus*. This type of infection is usually comparatively mild in nature and tends to recover, if the effusion is relieved. It follows pneumococcus infection of the lung and bronchi, or may be primary in onset. The presence of the pneumococcus is of great significance in the prognosis, as the mortality is quite low, the patient is usually not extremely ill, and recovery is fairly rapid.

The *staphylococcus* produces symptoms and a clinical course not unlike the pneumococcic infections. Convalescence is usually more prolonged and complications and sequelæ more frequent than in the pneumococcus variety, but with adequate drainage the prognosis is good.

The tuberculous type. This is, of course, secondary to tuberculous inflammations of the lung or pleura and may be acute or chronic in nature. The pleura may be studded with tubercles and bathed in a clear, straw-colored fluid of low specific gravity, and of large quantity; it is apparently sterile by slide examination, but the mononuclear leucocytes are present in fairly large numbers and inoscopy usually shows the tubercle bacillus. Inoculation with a considerable quantity of the fluid will give a positive reaction in guinea pigs and the tuberculin test is present in at least 65 per cent. of the cases. The cytodiagnosis is, of course, important in this as in all other types of pleuritic effusions. In a small percentage of cases of tuberculous pleurisy, exudation is absent, the inflammatory reaction being simply the production of a roughened fibrous connective tissue.

Chronic Types.—These are of interest because of their extreme chronicity and disturbance of general health when not given the benefit of treatment. The fibroadhesive types present strong bands of connective tissue or synechiæ extending from the parietal to the visceral pleura; or chronic effusion, which, when left alone, remains for months without undergoing absorption or material change. Lung collapse or compression is favored when these bands or accumulations are not relieved, and this with permanent damage. The collapsed or compressed lung, if permitted to remain in this condition for a considerable length of time, may resist all efforts at reexpansion and remain collapsed with a retraction of the chest wall, atrophy of the intercostal muscles, and deformity of the spine.

Symptoms.—1. Pain: In the acute types without effusion pain is intense from the onset, knife-like, stabbing in character, and depends upon respiration. If effusion takes place the pain descreases rapidly in proportion to the amount of exudate present.

2. Temperature: The onset of acute pleurisy with or without infection is always accompanied by elevation of temperature at some time. Even the apparently sterile effusions are associated with temperatures of 101-102° and the infected ones much higher, reaching in some cases 104-104.5°, though this is unusual.

3. Respiration: The respirations are markedly affected from the onset. They are rapid, shallow, and show restricted movement on the affected side. There may be dyspnea from the onset, produced by the pain primarily, and later from lung compression.

4. Cough: Incessant, dry, hacking cough usually begins with the initial pain and may be relieved only by an opiate. It is commonly referred to as a reflex cough, the irritation or compression being the primary cause.

5. Pulse: The pulse is rapid and weak, sometimes assuming a thready character.

Physical Signs.—1. Inspection reveals an anxious expression of the face, great restlessness, and rapid, shallow respirations with restricted movement of the affected side. In large effusions there may be bulging of the intercostal spaces.

2. Flatness may be elicited by percussion, and when effusion is present the location may be changed by change of position of the patient.

3. Auscultation may reveal diminished breath sounds and a friction rub with a disappearance of the latter when effusion occurs. Bronchial breathing may be present (transference from the compressed lung).

4. The tactile fremitus may be decreased or abolished entirely, depending upon the amount of effusion present.

Leucocytosis may or may not be present in the types with effusion. When present it is usually between 10,000 and 15,000. In about 10 per cent. of cases a leucopenia may be present, the severity of the disease or amount of effusion not affecting the leucocytic count to any great extent.

Aspiration.—This diagnostic procedure is, in my opinion, most important, as it will reveal: (1) If exudate is present; (2) Character of exudate (specific gravity, color, consistency); (3) What organisms, if any, are present as determined by microscopic examination and animal inoculation; (4) Amount of pressure present.

X-ray.—The value of the *x*-ray is obvious, in that it shows organic displacements, compression, quantity of effusion, etc.

Treatment.—Effusions: When one is convinced by the history, physical signs, aspiration, and the *x*-ray that pleuritic effusion is present in quantity, embarrassing respiration, with continued fever and the signs of lung compression, and the expectant treatment combined with potassium iodide and restriction of fluids has failed, thoracotomy or aspiration by trocar and cannula may be all that is required. The reinjection of 30 c.c. of the aspirated fluid after cooling has caused improvement in a number of cases, especially of the tuberculous variety, no doubt acting in these cases as an antitoxin.

If aspiration has to be repeated often it would be well to inject 30 c.c. of 5 per cent. formalin in oil or glycerin. This method produces irritation and some pain, but invariably causes a more rapid absorption of the fluid.

Fibroadhesive: When a pleurisy with effusion is slowly absorbed, the restricted breathing and lung compression tend to permit organization of the remaining fluid and bands of fibrous tissue, or synechiæ form between the pleural walls, which become very firm in nature and on ordinary or deep respiration cause pain and restricted breathing. Breathing exercises may or may not cause these organized deposits to disappear. If forced breathing is not sufficient to remove them or to so stretch them that the pain is relieved, then we may resort to rib resection or spreading and removal by the cautery.

Technique.—After incision of the parietal pleura, a careful examination by the gloved hand is made in an attempt to determine the location and density of the adhesions present. They should be grasped by forceps, delivered into the wound, and divided between forceps. After division is accomplished another forceps should be placed on the divided band as near the pleural walls as possible. The knife cautery is used to excise them at this point and a close examination is made for bleeding. If any is present, the cautery must be reapplied until all oozing had ceased. I shall not soon forget this lesson of complete hemostasis before the wound is closed, one case of postoperative hemothorax necessitating reopening of the chest being sufficient to make me realize the importance of this point in technique.

The simple thoracotomy for removal of synechiæ should not be drained ordinarily, as it does not materially affect the end results so far as postoperative complications are concerned and may be the cause of reformation of adhesions. The operation completed, the parietal pleura is closed with continuous fine catgut and retractors removed. If the muscle layer has been separated it should be closed by interrupted catgut. The skin is closed with dermal suture or continuous silk and a dressing applied over a broad strip of adhesive to limit respirations during the first 48 hours.

In opposition to popular opinion, I am firmly convinced that the application of a wool pneumonia jacket prevents in a large measure postoperative bronchitis and pneumonia, and I would urge its constant use in each and every operation upon the thorax, be it performed under local or general anesthesia.

Breathing exercises in the open after convalescence has proceeded to a point of safety are, in my opinion, good treatment.

Nutritious diet, some form of iron and arsenic, and light exercises are, I believe, very important adjuncts in the postoperative treatment of these conditions.

Empyema.—I do not think that it is within the scope of this paper, nor this the time or place for a lengthy discussion of empyema, as the literature is already overburdened with the subject. In almost every issue of our better journals there ap-

pears at least one article on some phase of treatment of this disease, all of which have an element of merit and none of which is ideal or guarantees a reasonable percentage of recoveries by any of the methods now in vogue. The much used and (in some circles) highly praised Dakin's solution is, of course, an absurdity and should be placed in the same category as acriflavine, the drug of 100 per cent negative results in the treatment of any infection. I do not wish to be misquoted or misunderstood in regard to Dakin's solution. I believe it has a definite place in the treatment of the bacillary gas infections and, to a limited extent, in some types of bone infections; but it never was, nor will it ever be, scientific treatment in thoracic surgery any more than it could be in abdominal surgery, and I am sure that anyone who is familiar with the experiments of Mann on the peritoneum will not attempt its use in the abdomen.

Serous and mucous membrane infection is not the place for Dakin's solution in the light of past experience. The use of mercurochrome is attended by a miraculous reduction of discharge and temperature, but I have used it in only two cases and am not yet prepared to give a résumé of results.

Vaccines are efficacious and should be given a thorough trial in empyema, and I am sure their use is attended by fewer complications, reduction in mortality and postoperative morbidity, any or all of which are so earnestly being sought for.

The intelligent use of vaccines in infection of the chest or in any other infection represents a distinct advance in therapy and will, I believe, undoubtedly assume a place of importance second only to surgery, which place it so justly deserves.

The types of pleurisy associated with tuberculosis should be given the benefit of operation in the removal of fluid or the division of adhesions, and if this is done early the patient has a much better chance of ultimate cure than if they are left to nature. Formalin and glycerin, 5 per cent, in this type of pleurisy is especially valuable. Then, too, the general health is much improved, the pain is relieved, and the psychic element is removed, which is so very important in the cure of tuberculosis.

Tuberculin correctly administered is an important adjunct here, and its use is invariably attended by marked improvement.

Summary.—In recapitulation I would emphasize:

1. Correct diagnosis by history, physical signs, and the *x*-ray.
2. Early operation with removal of fluid accumulation and appropriate treatment of adhesions and removal of synechiæ.
3. The knife cautery, to the exclusion of all other methods of operative technique.
4. Advantage of postoperative breathing exercises and nutritious food.
5. Use of pneumonia jacket in preventing postoperative sequelæ.
6. The continuous, intelligent use of vaccines.
7. Continued experimentation with mercurochrome.
8. All chronic fibroadhesive types of pleurisy, as well as those with accumulation causing disturbance of general health, should be given the benefit of early operation.

PURE APHASIAS À PROPOS OF A CASE OF PURE ALEXIA.*

By ALFRED GORDON, M.D.,

PHILADELPHIA.

Aphasia may be produced by a lesion situated in any portion of the speech-zone. The latter may be involved in two different ways: either a lesion destroys a part of this zone and its intrinsic fibers, or else when the lesion is sub-cortical, it isolates an area of this zone from the remaining cortex. We will be concerned exclusively with the latter localization of lesions. This is the so-called pure aphasia. The general essential characteristic of pure aphasias consists of preservation of the inner language, while in aphasias of cortical origin the inner language is always altered. The latter variety is incomparably more frequent than the former. In pure aphasia, whether we are dealing with motor, auditory or visual images of language, the centres of these images are isolated in their physiological connections. In the motor variety the disorder is only in the spoken language, while all other varieties of language are intact; the cortical center of Broca can no more control the movements of the tongue and lips; the association fibres subjacent to the cortical area are destroyed.

In the sensory varieties of aphasia the cortical centers of word-hearing or of word-seeing may be equally separated from the common centers of hearing and seeing, respectively.

There are very few cases of pure word-deafness in the literature. Lichtheim and Sérieux reported similar cases in which the patients preserved the power of volitional speaking, of writing, of reading aloud. They had neither paraphasia nor paragraphia. In cases of word-deafness of cortical origin, paraphasia and paralexia are present because the patients are unable to verify through the affected cortical center what they say or mean, whereas in cases of pure word-deafness they can do this: they understand questions in writing and reply correctly; spontaneous writing and copying are normal. What is wanting is writing from dictation, the patient hears words and sounds but cannot understand what is said to them.

Cases of pure word-blindness similar to those with word-deafness are likewise rare. Very few instances are recorded in the literature since Dejerine first called attention to it.

The following case, although not as yet verified by autopsy, is a clear example of the condition and deserves to be put on record:

Man, aged, 72, right-handed, presents an emphysematous state of his lungs and endomyocarditis with arrhythmia. Besides, arteriosclerosis is very much pronounced. Blood pressure: systolic, 190, diastolic, 120; urine contains a small amount of albumin, Wassermann is negative, eye grounds are normal. Several years ago he had a mild attack of right hemiplegia, from which he made a complete recovery. About one year ago he had an attack of vertigo with severe headache, following which he developed a condition which has remained unaltered up to the present time. The patient is unable to read printed and written words. Spontaneous speech, repeated speech, singing, understanding spoken words, are all carried out correctly. Reading aloud and mental reading are impossible. The

*Presented at a meeting of Philadelphia Neurological Society, April, 1920.

patient sees the written words, is able at times to name correctly some letters, but is utterly unable to make out the sense of the word. Copying is very difficult, but writing under dictation and spontaneous writing are almost entirely correct. However, the letters written appear much larger than those of the patient's former writing. The inability to read is observed also when the patient endeavors to go over his own writing, in which he has difficulty in recognizing his own name and the most familiar words. If at times he recognizes an occasional word he succeeds in it only when he follows each letter with his finger.

It is evident that in this case all images of the language are preserved; patient understands spoken words, writes spontaneously and under dictation, is able to pronounce.

Two other interesting phenomena are present here: First, the verbal blindness was only with regards to words; but not to figures; the patient was able to add, subtract and carry out other arithmetical operations. Second, there is a right homonymous hemianopsia.

The clinical picture of the present case corresponds precisely to the description given by Dejerine in 1892 in which he isolated from Wernicke's sensory aphasia a form of aphasia to which he gave the name of "pure word-blindness."

In alexia of cortical origin, which is due to a lesion of the angular gyrus, we usually observe an impairment of the inner language; there is ordinarily a certain degree of word-deafness, of paraphasia and of agraphia for spontaneous writing and for writing on dictation. Moreover not only written words, but also figures are not recognizable by the patient. Finally a homonymous hemianopsia is very rarely, if at all, observed in cortical lesion of the angular gyrus.

In the present case the lesion which is a softening due originally to an embolic occlusion is probably situated in the inferior longitudinal bundle, viz: fibres connecting the center of general vision with the center of visual images of speech (angular gyrus). Such a conception explains readily the absence of all other aphasic disorders and the presence of the hemianopsia. We are dealing, therefore, with a case of "pure alexia."

It may be of interest to note that there has been no improvement of the patient's condition.

1812 Spruce Street.

THE BACTERIAL FLORA OF TUBERCULOUS SPUTUM.

By JOSEPH E. STROBEL, M.D.,

HARTFORD, CONN.

In reporting this work, I wish to state that it was done while on temporary relief duty at the Meriden Tuberculosis Sanatorium, Meriden, Conn. While there the following problem presented itself: Is there any morphological change in the tubercle bacillus before, during or after hemoptysis, and is there a constant presence of gram-positive cocci? The problem was followed out using guinea-pigs and rabbits for the test.

While there but five hemorrhages occurred. In all, acid-fast bacilli were found, presenting a marked granular or broken down rod which held the stain well against an acid. Gram-positive cocci were observed in all specimens. These were arranged singly, in pairs, in chains and in tetrads. The chains did not appear to be any longer than the usual length of a human tubercle bacillus. Nothing different was noted in the other cocci.

From these specimens guinea-pigs were inoculated, using a sterile syringe and needle and without any previous chemical treatment of the sputum. One pig died twenty-two days after inoculation. No macroscopic tubercles or cheesy masses were found. The liver and spleen were greatly enlarged and adherent to the stomach. Large tubercle bacilli were found in abundance in smears from all organs. Blood smears were negative. The gram-positive organisms that were injected with the sputum were not recovered. The second pig died thirty-five days after inoculation. At autopsy this presented an entirely different picture. Lymphatic glands, liver and spleen were greatly enlarged, and the intestines were matted together by numerous adhesions. On the right they were strongly adherent to the parietes; on the left a large abscess presented which was about the size of a walnut. This abscess was well encapsulated, with a thick wall and adherent to the intestines and parietes. The liver and spleen were greatly mottled, as also were the lungs. The kidneys were enlarged and congested. Smears from all these organs contained tubercle bacilli in abundance. All tubercle bacilli found in pigs were well separated and appeared to have no tendency to clump or even arrange themselves in pairs. No gram-positive organisms were found in smears from these two autopsies. No report can be made on the other three pigs, as I had to leave Meriden at that time.

After returning to Hartford four more hemorrhage cases were encountered. The sputum of all contained tubercle bacilli and gram-positive cocci as in the other cases. In one of these cases the diagnosis had been in doubt as tubercle bacilli had been absent on repeated previous examinations. The hemorrhagic sputum, however, revealed them in abundance. A rabbit was inoculated with sputum from each of these cases. One rabbit died in twenty-four hours showing marked congestion of the lungs and liver. Blood smears contained large encapsulated diplococci in great numbers. The second rabbit died on the ninth day. In this animal there was a severe peritonitis with adhesions and pus in the peritoneal cavity. Encapsulated dyplococci but no tubercle bacilli were found in this pus. Blood smears were negative. The other two rabbits died of lobar pneumonia and pneumococcic septicemia. In all patients after hemorrhage had ceased the microscopical picture of the sputum had not changed.

To sum up, we have two widely different infections in these animals. The guinea-pigs died from an extremely virulent tubercle infection, while the rabbits undoubtedly died from the effects of the pneumococcus. One must conclude from the above that no relation existed between the gram positives and acid fasts in these instances. The marked beading of the tubercle bacilli originally was in all probability due to the poor culture medium in which it was growing. As soon as the culture medium was improved (guinea-pig) they immediately began to grow luxuriantly.

19 Wethersfield Avenue.

PHIMOSIS AND THE GUILLOTINE, A NEW INSTRUMENT FOR CIRCUMCISION.

By CHESTER TILTON STONE, M.D.,

BROOKLYN, N. Y.

TRUE phimosis, as its Greek meaning, *to bind*, expresses, is a narrowing of the opening in the prepuce. It is probably the commonest of all congenital malformations of the urinary tract. We have come to apply the term to long foreskins in general, whether or not retractable. There are also included under this classification, long loose foreskins, short loose, long tight, or short tight ones with various intermediary stages. Frequently, especially in children, the prepuce may be found adherent.

Phimosis may be acquired as well as congenital. Chronic or recurrent balanitis and chancroids, in their process of healing, are common causes. In these cases the prepuce is greatly inflamed, swollen and edematous. Cases of this nature are often seen in consultation.

At first glance the patient seems to be suffering from an acute urethritis. There is a profuse discharge and, in many cases, almost a constant drip. So rich is the pus in color that one may readily make a false snap diagnosis of gonorrhea. A properly taken history, together with a painstaking microscopic examination of smears and examination of the urine, rule out this possibility. Palpation clinches the diagnosis, for invariably in these cases the lesion or lesions may be felt beneath the prepuce. Of course the patient may have a gonorrhea complicating this condition. The microscope will tell the story. Each condition must be treated separately.

It is important to remember that however bad the case, and however imperative may seem the operation, a few days should be devoted to quiet, tonic treatment, subpreputial injections and hot soaks, to reduce the discharge and better fortify the patient for a more rapid recovery. Then operate. If operation is not performed there will be slough, loss of gland tissue and deformity. Not infrequently we see such cases, where a chancroid has sloughed through the prepuce or where a verrucca by pressure has perforated the foreskin. In other cases ulceration has pierced through the dorsum of the prepuce with the gland protruding. In these latter cases edema soon follows. This should be treated by hot lead and opium soaks or hot solutions of magnesium sulphate. When the swelling is reduced, circumcise.

Many conditions may be laid to phimosis. In children frequency and enuresis are probably the most common. In these cases the skin is long, tight, and as a rule adherent. Due to difficulty in passing urine the foreskin becomes ballooned, and there is back pressure through the urethra causing irritation of the urethra and sphincter. If neglected the condition progresses to the bladder, causing irritation and hypertrophy. The ureters and kidneys are next affected, producing dilated pelves. Masturbation is frequently caused by irritation either in or underneath the foreskin. Circumcision does not always entirely cure this practice. Frequently it is necessary to treat the ensuing neuroses over long periods.

The fact that urethritis is contracted oftener and more readily by those having phimosis is indisputable. This is due not only to the impossibility of properly cleansing the organ, but to the fact that the long foreskin acts as a dam which entraps and retains the germs, holding them in sites favorable for further spread and incubation. Other venereal infections, as chancres and chancroids, are likewise aided.

Among the remote results in adults are retention and incontinence, due to spasmodic contractions or relaxations of the cut-off muscle, or to irritable bladder induced by prolonged irritation of the glans penis.

When the patient is suffering from a long standing phimosis, prolonged or violent straining efforts upon urinating in time will produce hemorrhoids, prolapsus ani or herniæ. Numerous nervous affections, chief among these are spastic palsies, simulated hip-joint disease, muscular incoordination, convulsions, neurasthenia, chorea, hysteria, and hypochrondria, may be directly traced to phimosis. In children, especially, these are prominent. In adults irritation often causes a reflex nervous condition. This is called herpes preputuialis. Treat first palliatively by injecting astringent disinfectant soothing or cleansing solutions beneath the prepuce. Circumcise as soon as the irritation subsides.

In cases of phimosis when the epithelium of the balano-preputial sac becomes macerated, urine is impeded in its flow and drops are retained. These become mixed with smegma. Lack of cleanliness leads to recurrent attacks of inflammation. As a result there is a proliferation of epithelial cells called venereal warts. Epithelioma may develop if the case is neglected. It may go on to a gangrene. Preputial calculii are similarly formed, save that there is a calcification of smegma and decomposed urinary salts.

How often we find a general practitioner, who for weeks, months, or in some cases years, has struggled with a stubborn case of urethritis. Symptoms apparently clear, the patient feels fine; the physician beams with pride at his prompt results, when lo! a few days pass and the "cured case" either returns or goes elsewhere with the same old story. A great majority of these cases have phimosis. Circumcision in all of these, whether the skin be loose or tight, will not only win half the victory but start the patient far on the road to recovery. The reasons are obvious. It helps discourage the morning "milking," a habit so common among chronics; it helps remove irritation from without; it enhances cleanliness, promotes better drainage, lessens chances of complications and boosts the patient both physically and mentally.

Another class of visitors to many offices is made up of those who come complaining of impeded coitus and premature ejaculation. A large percentage of these will be found to be suffering from an enlarged verum montanum, irritable prostate, or over-distended vesicles. In going over a large number of these cases one is surprised at the great many suffering from phimosis. The surprise is still greater, however, at the rapidity with which symptoms subside following circumcision.

These cases may be divided into two groups: those suffering from reflex irritation induced by the tight foreskin, and those who have an acute or

chronic infection added to this reflex irritation. It is needless to add that circumcision *per se* will not entirely cure the condition. Other treatment will be necessary. Circumcision does pave the way, however, to a recovery which would otherwise be impossible or at least difficult.

A type closely allied to the above, and treated in a similar manner, is that suffering from an arrested development of the penis and testicles. Here are found as a rule the masturbators, with their premature erections, sexual perversions and excitements. Few of us indeed realize how often a phimosis may be a great incumbrance or how it may govern a really serious condition.

Recently there came to my attention an old man, seventy-six past, who had suffered from phimosis all his life. No great trouble had resulted until after he had developed incontinence. The constantly dribbling urine macerated the epithelium of the glands, producing erosion, and later beginning gangrene. After doing circumcision, which seemed to be the only solution, not only did this condition clear up, but his frequency also diminished.

The history of the operation of circumcision is as interesting as the modes and customs are varied. We find it dating back long before the Christian era, even before the time of Moses and Abraham. It is a religious rite, among not only the Hebrews, but various races on different continents. It has always been a custom among the Egyptians, Arabs, Persians, East Indians, North and South American Indians, certain African tribes, Australians and some South Sea Islanders. As a religious rite it dates back more than 2000 years B. C. With the Hebrews it is performed on the eighth day while the Egyptians leave it till the sixth to eighth year. While the history is interesting, space here forbids its recital. So with the history of the method of removing the redundant skin. Probably there is no operation in history with so many techniques. A paper could be written on this subject alone. Though the transition from the old crude methods of chopping the skin off with a ragged shell, or biting it off with a mouth filled with wine, to removal by knife and scissors, was marked, many consider the transition still greater from the former modern methods to that of the guillotine.

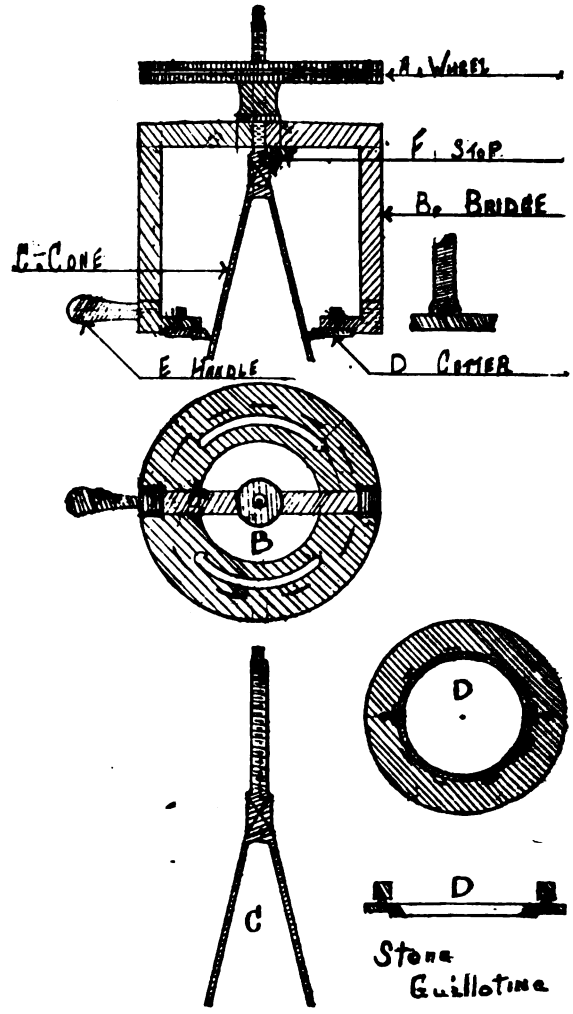
Since writing my article which appeared in the MEDICAL RECORD of September 18, 20, I have greatly improved the instrument. By referring to the accompanying illustration one may readily see the additional advantages. An illustration of the new improved instrument with the method of using it follows:

After first scrubbing up the patient, mark the foreskin with a pen at the place where the cut is to be made; select the size cone (C) suited to the patient, sterilize this with its cutter (D); when properly sterilized insert cutter in bridge (B) and set aside. Now taking the cone, draw back the foreskin behind the glans; place the cone on penis and slide the skin over it. Attach bridge to cone so that edge of cutter is in apposition with inked line; turn down wheel (A) until cutter gently compresses the skin. Inject local anesthetic just posterially to the cutter, around the whole penis. When sufficient time has elapsed for the anesthesia to be effective, turn down wheel firmly until a sharp "click" is heard. The skin is now off. Having removed the instrument, a clean smooth cut will be found. No bleeding will be in evidence and the edges will be found to be perfectly opposed. It is well to gently massage the cut surfaces in order to locate the bleeding points which should be tied off.

As mentioned in my former article our method of suturing is to place four anchor sutures, left long for fastening the bandage, with the intervening spaces closed by continuous suture.

With the instrument are eight cones and eight cutting plates that vary in size from a large adult to a small infant.

An operation performed by this method should give union in two days. There will be found no



ragged edges, bulgings, or unforgivable buttonholes. In my series of over 500 cases performed with this instrument there have been no infections and no postoperative bleeding. Five circumcisions may be performed in one hour. The patients are invariably pleased with the results. The instrument itself is easily taken care of, and is practically fool proof. It does away with the need of an assistant.

A word of caution might well be given here to aid in performing a pleasing circumcision. Where feasible it is always best to make the removal midway between the glans and the tip of the prepuce. For, in case of insufficient removal there is danger of contraction along the line of incision and the operation

is of no avail. In case of removing too much the patient will curse you to his dying day. You have only to recall the moving picture of the bent gun barrel to imagine the result.

Care should also be taken while placing the cone in position to avoid injuring the glans. It is wise after operation to be sure that all bleeding is checked especially in hemophiliacs, as hemorrhage following circumcision is not only a source of discomfort, but in some patients fear or even danger.

Bearing in mind that the prepuce is in two layers, one continuous with the skin of the organ, the other a reflection of the mucous membrane from the sulcus behind the glans, which unite, forming the margin of the prepuce, this relation should be imitated in doing a circumcision.

The guillotine uniformly gives better results than any method as yet tried.

62 PIERREPONT STREET.

Medicolegal Notes.

Admission of Expert Evidence as to Lost X-Ray Picture.—In an action for personal injuries, resulting in a dislocated hip, it appeared that an examination was made of the injured hip at the hospital by the attending physician, Dr. Guthrie, who took the patient to an *x*-ray expert, Dr. Pepper, where a plate was made of the hip, after which the patient was sent home. Drs. Guthrie and Pepper examined the plate and determined from the information received therefrom and from their examination of the injured leg that there was a fracture of the hip bone. On this the subsequent treatment of the patient was based. The *x*-ray picture was subsequently lost, and the question arose as to whether the trial court erred in permitting Drs. Guthrie and Pepper to testify as to what the picture disclosed to them. It is quite true that before a radiograph can be used as evidence it must appear that it was so taken as to represent correctly the object reproduced. Of course, it is not meant by this that some one must testify that it is in fact a correct representation. Manifestly this would be impossible, for the reason that the object thus photographed is not visible except with the aid of the *x*-ray machine. What is meant is that it must appear that the machine was so placed and operated as to reproduce correctly the object brought within the radius of its activity. Nor need this necessarily appear by a direct statement of the operator to this effect, although it may be, and ordinarily is, shown in that way. It may, however, as well be shown from a detail of the circumstances. In this case Dr. Pepper, who took the radiograph, was shown to be an expert, with large experience in the work. The picture was taken with a view of determining the nature and extent of the injury with a view of treating the same, and the treatment was administered with favorable results. This, the court held, might not prove absolutely that the plaintiff was injured as disclosed by the radiograph, but the fact that the injury sustained by her responded to the treatment ordinarily administered for the relief of an injury such as that shown by the *x*-ray was, to say the least, very strong evidence that her injury was actually of that character, and sufficiently authenticated the picture to justify its admission in evidence.

Could the doctors who examined the radiograph testify as to what it indicated? It was contended that the bones themselves were the primary evidence, that the picture, if in existence, was secondary evidence, and that the statements of the doctors in regard to it were tertiary evidence or knowledge derived only from a view of secondary evidence. It was held that the original injured condition of the bone having been changed by lapse of time and the treatment administered, and the only reproduction of that condition being lost, the best evidence obtainable as to what condition actually existed at that time was the impression made upon the minds of the two doctors from their examination of the plaintiff's hip and the radiograph thereof; and it was not error to admit this evidence.

After the trial had been entered upon the defendant requested that a radiograph be made of the injured member, and the plaintiff was willing that this be done. It was held not error for the trial court to refuse the request, no reason being given for not having made it before the trial, and it did not appear how long the trial would be delayed by granting the request.—Quinn v. Flesher, West Virginia Supreme Court of Appeals, 102 S. E. 300.

Massachusetts Statute Requiring License to Practice Optometry Held Valid.—The Massachusetts Supreme Judicial Court holds that Massachusetts St. 1912, c. 700, for the regulation of the practice of optometry, is violative neither of the State nor the Federal Constitution. Such work or practice has such an intimate relation to the health of mankind as to bring it within the power of legislative supervision through the exercise of the police power. Vision is essential to the highest usefulness of the individual. The eye is proverbially a delicate organ. It is closely connected with intellectual, nervous, and physical functions. Advice as to its care and prescribing for the correction of its defects by tests and examinations without the use of drugs is closely connected with health. The reasons which have led courts generally to uphold statutes regulating the examination, qualifications, and registration of physicians and surgeons against attacks based on alleged inequality of the laws, class legislation, interference with natural rights, and the constitutional liberty of the citizen to earn his living in any lawful calling or to pursue his chosen avocation, were held equally applicable to this statute and equally decisive in sustaining its validity. In McNaughton v. Johnson, 242 U. S. 344, 37 Sup. Ct. 178, a similar statute of California forbidding the practice of optometry without first having obtained a certificate from a public board was upheld as within the police power of the State and as not violating any constitutional right of the individual theretofore practising optometry without a certificate.—Commonwealth v. Hontenbrink (Mass.), 126 N. E. 669.

Injury to Eye by Being Struck by Insect Accidental.—A motorcyclist ran through a swarm of flies or insects, one of which struck his right eye with such force as to give him immediate and continued annoyance and distress, and ultimately impaired his capacity to work at his usual occupation of bookkeeper, so that he had to give it up, the injury finally resulting in blindness. It was held that the injury was accidental within the meaning of an accident policy.—Tracey v. Standard Acc. Ins. Co., Maine Supreme Judicial Court, 109 Atl. 490.

Physician Can Sue Insurance Company Direct for Bill Under Texas Workmen's Compensation Act.—The Texas Workmen's Compensation Act provides that if the association fails to furnish medical aid after notice of injury to the association or subscriber, the injured employee may provide medical aid at the cost and expense of the association. In a case where a claim was made by a doctor to recover on an alleged agreement, either implied or specific, to pay for services rendered by him to an employee, it was held that under the statute an insurer is liable for medical aid rendered by a physician procured by the injured employee either where the physician was procured by the direction of the employer or where the employer had notified the insurer and it had failed to furnish medical aid. A physician, furnishing medical aid to an injured employee, may, under the act, recover direct from the insurer. Although the act allows a physician to recover for only two weeks' services, yet where the services rendered an injured employee were surgical in their nature, and treatment given after the expiration of the two week period was only incidental, for the purpose of seeing that the limb was in place and that no complications had arisen, the actual services having been rendered, the physician may recover, although the services covered a period in excess of two weeks. Under the act an injured employee may at the time of the injury or immediately thereafter call in any available physician to render such first aid treatment as may be reasonably necessary at the expense of the association.—Home Life & Accident Co. v. Cobb (Tex.), 220 S. W. 131.

BEZREDKA'S DISCOVERY.

IT is a truism of medical science that the correctness of an hypothesis is no criterion of its intrinsic value, and it is not difficult to bring forward examples of advances and measures of practical application secured by deduction from suppositions which, in the light of fuller knowledge, are found to be untenable. The most recent and at the same time perhaps the most notable instance of this kind is the socalled side-chain theory of Ehrlich which resulted in the Bordet-Wassermann test. This test has come forth triumphant from most searching and rigorous examination, while the side-chain theory has been practically discarded.

These facts must be recalled when a new scientific doctrine, evidently subversive of generally accepted views, is offered to the medical profession. The mere fact that the latest observations would seem to disprove an established conception of disease in no way weakens the value of any results which may have accrued as a consequence of its practical application. When, for example, we are informed, as the Pasteur Institute, of Paris, has recently proclaimed, that a distinguished worker in that famous home of bacteriology has conceived new theories on subjects so important as the protection of the human organism against typhoid fever and dysentery, and that these theories will result in a revolution in bacteriology, we need not—even supposing complete proof is about to be produced—rush to the conclusion that earlier opinions were devoid of value or were in vain.

Bezredka advances arguments which tend to show that the future defense against diseases of the typhoid group will be much simpler than the present antityphoid or antiparatyphoid vaccination. This by no means detracts from the magnificent achievements accomplished during the war of ridding armies of one of their most deadly foes. On the other hand, it does promise to be an easier method of obtaining the same result.

If it can be shown that the mere act of swallowing some dead bacilli can secure the human race against such redoubtable foes as typhoid, the paratyphoids, and dysentery—and that without the very slightest personal inconvenience or the most trifling malaise—then unquestionably a new chapter in prophylaxis has been begun. Bezredka adduces evidence in favor of the view that certain bacteria have special specific areas in the body within which they are active. No matter how introduced into the organism, whether intravenously, subcutaneously, or by ingestion, they seek out these special tissue areas and would seem to be quite harmless until they become localized in them. Consequently the question of protection is local rather than general. If the tissue area which the particular bacterium requires for its development is rendered unfit, disease will not develop. Our efforts have, up to the present, been directed by the idea that protection or immunity should be general in the human organism, and it may very well be that our past failures have resulted from this conception. Our undoubted successes do not lose in merit or in value from the recognition of a past oversight. Indeed, we may perhaps go farther and suggest that the truth of every hypothesis is to be measured, not in terms of acceptance, but in respect to the solid advantages derived from it.

THYROID OPOTHERAPY.

THIS trite subject is still of the utmost interest because of the illimitable possibilities present when there is really a shortage of thyreoidin in the body. The same may, of course, be said of the other major endocrines, but thyroid is the premier and not only has by far the widest range of usefulness but must enter fully into all pluriglandular therapy. In the Opotherapy number of the *Journal de médecine et de chirurgie pratiques* for November 10, 1920, xci, 21, Harvier, evidently jealous of the reputation of French-speaking pioneers, gives precedence to Reverdin and Bourneville in association with the Englishman Gull. Reverdin discovered cachexia strumipriva while Bourneville first described myxedema in the child, and Gull receives due credit for the same discovery in the adult. From these beginnings the subject developed with amazing rapidity. Lannelongue, a pioneer in child surgery, was active in attempts to graft the thyroid in young myxedematous subjects. The author discusses feeding with fresh and dried thyroid and hypodermic thyroid medication, the last named being largely abandoned to-day. The question of thyroid tolerance comes strongly to the front and the author, to be safe, would intermit the treatment when the pulse rate reaches 90. The tolerance must invariably be determined if the practitioner does not wish to face a possible charge of malpractice, for several deaths are recorded in which the thyroid medication was accused. The signs of intolerance comprise the following: cardiac palpitation, hot flushing, sweating, diarrhea, tremor, loss of flesh, and quick pulse. These are easily avoided by graduated dosage and other devices to obtain the maximum effect with the minimum of waste and risk.

From the empirical viewpoint thyroid medication appears to be of value in a host of maladies.

Amenorrhea and menstrual inefficiency in general may benefit from it, but at the same time there is a state of menorrhagia which may likewise improve. Aside from remarkable results in arrested growth—in which there was no suggestion of cretinism—and in dermatoses, obesity, and arthropathies, such as have been reported for years, there is not much to state which is in the least novel. Harvier says that of all the multifold indications for thyroid medication one stands out in relief—the indication of chronic rheumatism. However, he bases his opinion on the more or less dubious reports of Levi and Rothschild.

ADVERTISING.

"MAKING one's self known" is a professionally ethical process. "Advertising" is not. How to do the former without seeming to do the latter, is a question which has doubtless suggested itself to all doctors, particularly to all young doctors. In our professional seclusion we look with great disgust upon the successful efforts of "cure"-vendors and quacks of every sort to push their way to the attention of the ailing public. This very proper and natural disgust may quite conceivably be accompanied by a secret desire to accomplish the same end without cheapening one's self or subjecting one's self to like criticism; for, it may well be said, the doctor is entitled to the privilege of having people know that he exists, in case they might elect to give him a try at their various ills.

To such medical men we wish to emphasize what we have emphasized before, namely, that people who are too intelligent to resort to advertising tinkers, require of the "reputable physician" that his repute come from reliable sources, whether the source be another physician, or a hospital in a position to judge his work; or whether it be his own patients, those potent means of advertising per os.

Let us, instead of heaping ignominy upon the heads of the charlatans, seek rather to rouse the newspapers to the evil, often disastrous effects of giving publicity to the trash advertised. In so doing we shall be fighting fire with water, for, as Dr. Servoss wrote recently (MEDICAL RECORD, xcviii, 23, December 4, 1920), "Without advertising or publicity of one sort or another, the charlatan in medicine cannot live." Stifling the quack by arousing the intelligent cooperation of the press would be far more effective than the method proposed by this author, who suggests that "the legitimate physicians do not give themselves sufficient publicity. They do not fight fire with fire."

In "fighting fire with fire"—*i.e.* in opposing publicity with publicity, the profession would be making its appeal only to the unintelligent. The intelligent are less gullible. At first sight, the profession is entitled to make such an appeal, with resulting benefit to the unintelligent. But it must be remembered that scientific medicine makes no sensational appeal. If it tried to "come from beneath the bushel," its modest statements would make a sorry figure in the limelight beside the lurid, death-defying claims of the master-quacks. In other words, a campaign of publicity on the part of the "legitimate physicians," though it might seem to be indicated, would only alienate and antagonize the intelligent and fail to appeal to the unintelligent. Let us fight fire with water.

AN EXAMPLE IN COURTESY.

MANY veterans of the World War who returned to civil life minus a limb or an eye, or perhaps with even more disfiguring physical disabilities, do not direct attention to these marks of distinction by wearing the Victory Medal or other symbol of service. The public, therefore, must surmise, without being certain of the correctness of the conjecture, that such men met accident in the course of war and not in civil life. Nevertheless, one has heard all too often, since our boys have been demobilized, "Ah! yes, the world so soon forgets!" The world has not forgotten and can never forget the sacrifices made during the terrible conflict. It is well, however, that we have such an excellent example of courtesy to our sick and wounded soldiers as that recently set by Major-General Leonard Wood, U. S. Army, commanding the Sixth Corps Area at Fort Sheridan, Ill. In a recent order dealing with military courtesy, reprinted in part in the *Army and Navy Journal* for November 20, General Wood said: "Fort Sheridan is still honored by the presence of many sick and wounded soldiers from the battlefields of the World War. The commanding general will set the example in showing special consideration of these disabled soldiers and will salute those who are unable to salute first as they would wish. It is desired that this policy characterize the officers of this command as a mark of respect to those men who have served so well." This example of soldierly courtesy to those sick and wounded in war may well be followed, in spirit, by all who minister in any capacity to the sick anywhere.

DIGITALIS IN POST-DIPHTHERITIC CARDIAC DISTURBANCES.

IT is all too clear that the profession as a whole—that is to say, mediocre and otherwise—has not abandoned the notion that "when there is something the matter with the heart give digitalis." In the light of recent investigation, it would seem that this notion alone must be the basis for persistence in giving the drug in cases of cardiac disturbance following diphtheria. It is distressingly common to see cases of post-diphtheritic myocarditis admitted to hospitals with all the signs of cardiac failure, having been subjected to assiduous digitalis therapy by the "outside doctor." One must also admit the frequency with which such therapy is resorted to in some of our better hospitals. The most recent and valuable study of the heart in diphtheria is that by McCulloch of St. Louis.[1] His careful electrocardiographic work showed that "The most frequent disturbance . . . is in intraven-

1. McCulloch, Hugh, Studies on the Effect of Diphtheria on the Heart, *Am. Jour. Dis. Child.*, xx, 2, August, 1920.

tricular conduction. The Q R S time is prolonged, the amplitude of the R-wave is much diminished, and the T-wave is inverted, often in all three leads." Thus, the effect of the diphtheria toxin would seem to be closely identical with that of digitalis itself. Moreover, bundle branch block, and complete heart block were shown by McCulloch to be by no means rare. If these observations are correct, the lesson is clear. When we give digitalis to patients suffering from post-diphtheritic cardiac lesions, we are guilty of that all-too-prevalent sin, "therapeutic injury." And the sooner we realize it the better.

Cranial Stigmata of Heredosyphilis.

Oltramara (*Schweizerische medizinische Wochenschrift*, Sept. 23, 1920, i, 39) first distinguishes between actual syphilitic lesions and dystrophies in the victim of hereditary syphilis. The latter may or may not be due to the participation of the endocrine glands. In the dystrophies antisyphilitic measures are valueless but endocrine remedies are sometimes useful. The Wassermann is negative in the uncomplicated case. The dystrophies may be handed down to posterity and thus become familial. Naturally they are not always specific for syphilis, for they may be the result of other race poisons. The author limits himself to craniofacial malformations such as facial asymmetry, oxycephaly, natiform cranium, "olympian brow," and especially flattened nose. Thickening of the root of the nose he thinks may be pathognomonic and due to hyperestosis of the sphenomaxillary bones, a ridge often being discernible. Other malfornations are prognathism, ogival palate, multiple malformations of the external ear, separation of the incisor teeth, etc. The general effect is at times simian, mongolian, or negroid. The absence of such types in Greek and Roman sculptures, the author thinks, is favorable to the belief that there was no syphilis in those centuries, but this remark seems trivial, for monstrosities and degenerative stigmata can be recognized in classical representations and a monograph, the name of which escapes us, is devoted to that subject. Modern sculptors on the contrary have made both real and ideal representations of malformations of the head, nose, and ears. The author mentions as examples the Paul Verlaine of Niderhausen and Rodin and Vibert's poet.

News of the Week.

Senate Passes Maternity Bill.—The bill "for the public protection of maternity and infancy," through cooperation between the Federal and State Governments, was passed by the Senate on December 18. The bill carries an annual appropriation of $1,480,000. Of this, $480,000 is to be apportioned equally to the States, and the remaining $1,000,000 will be apportioned in the proportion which the population of each State bears to the population of the United States. In order to obtain its share of the money appropriation a State may create or designate an agency which shall have power to cooperate with the National Children's Bureau in the administration of the act. The Children's Bureau has the authority to recommend the appointment of Advisory Committees, State and local. Provision is made for extension courses in the hygiene of infancy and maternity in connection with State universities. Not more than 25 per cent. of the amount granted to a State may be used for this purpose. It is further provided that no payment out of the appropriation of $1,000,000 shall be made to any State until the Legislature of that State has provided an equal amount from the State Treasury. The bill which now goes to the House contains much of the material offered by the League of Women voters as a suggested plank in the platform of both political parties last summer. An effort has been made to get the measure through the short session of Congress so that the matter can go to State legislatures, meeting this winter. The measure requires cooperation on the part of the several States through legislation. The Massachusetts Civil Alliance has issued a strong protest against this bill, calling attention to the fact that, as there are 2½ million births annually in the United States, the cost to tax-payers will be enormous. Whatever may be brought under government ownership and control, it says, the American home should never become socialized.

Cholera in Refugee Camps.—A delayed cablegram from Constantinople reports that cholera has broken out in the refugee camps for Russians at San Stephano on the western outskirts of the city, despite sanitary measures instituted by the American Red Cross.

Encephalitis Lethargica in Europe.—According to a special cablegram to the *New York Herald*, encephalitis lethargica, which has appeared all over Europe since last February, was the subject of discussion before a recent meeting of the French Academy of Medicine. The majority of cases are said to be mild, and fatal complications rare. It is reported that such scientists as Dr. Georges Guillain and Dr. Le Chelle assert that the disease can be transmitted by the breath, clothing, or bedding. Hiccoughs are said to be one of the initial symptoms, and it is added that the French press is full of suggestions for their control.

War on Drug Venders.—Dr. Carleton Simon, Special Deputy Commissioner appointed to the task of reducing the number of drug addicts in New York City, believes that his work in driving out or imprisoning venders of habit forming drugs is beginning to show results. He states that he and his detectives have learned that New York drug addicts are getting their supply from three rings, the European, the Canadian, and the Transcontinental. The places of entry, he says, are being closed up. He blames the abundance of criminals on existing drug conditions, which were brought about in some measure by prohibition. He does not believe that prohibition has increased the number of criminals, but that it has closed up their resorts and driven them to the streets and to drugs.

Budapest Doctors in Desperate Straits.—A recent cablegram from the American Relief Administration in London to the *New York Times* reports that Budapest physicians are in such desperate circumstances that many are forced to sell their instruments as people are so poor that they are unable to pay for medical attendance. The situation is complicated by the presence of many refugee doctors from the lost territories.

Hospital Lease Bill Submitted to Senate.—Senator Wadsworth of New York introduced a resolution into the Senate on December 14, authorizing the Secretary of the Treasury to lease from New York State a $3,000,000 hospital for the care of soldiers suffering from mental and nervous diseases which would be built in New York City. The resolution would also give the Treasury Department authority to lease any other hospitals for like purposes by other states.

Increase in Auto Accidents.—The Census Bureau at Washington reports that automobile accidents continue to show an increase during 1919 with a total of 7,969 for the registration area, comprising about 80 per cent. of the country's population. This total includes 3,808 deaths in sixty-six of the large cities of the country which statistics were announced several weeks ago. The deaths from automoble accidents showed an increase of 444 for 1919 over the total of 1918 in the registration area.

Fire in Walter Reed Hospital.—The four psychopathic wards of Walter Reed Military Hospital were swept by fire on December 12, resulting in a loss of about $25,000. In checking up the list of patients in the wards, one patient, Sergeant Alzin Messenger, formerly of the Seventh Coast Artillery, was found missing, and is believed to have been burned to death. The hospital authorities believe the fire started by his having smoked in violation of the rules and set fire to the bed clothing.

Proposed War on Rats.—An amendment to the Building Code of New York City is pending before the Board of Standards and Appeals, which would make imperative the ratproofing of all buildings within 600 feet of the water front. This measure has been drawn up at the suggestion of Health Commissioner Copeland who regards its adoption as an important step in the fight he is waging against the introduction of the plague which is raging in Southern Europe. Dr. Victor G. Heiser of the Rockefeller Institute has estimated that there are about 6,000,000 rats in this city, and that they cost a property loss of $35,000,000 annually. The proposed measure provides that no certificate of occupancy shall be issued for any structure erected within 600 feet of the water front unless its foundation walls are constructed of concrete or similar hard material, and covered with wire screening. All windows and other openings must be protected with wire screens, and must be arranged to permit fumigation with hydrocyanic gas. It is estimated that if this measure is adopted it will cost property owners from $50,000,000 to $100,000,000.

To Assist Medical Schools of Central Europe.—The Rockefeller Foundation announces a cooperative plan whereby it expects to aid in the rehabilitation of scientific equipment for medical teaching and research in the medical schools of Central Europe; to aid in furnishing medical journals to universities throughout Europe, and to extend an invitation to the authorities of Belgrade University Medical School to study medical education in America and England, as guests of the Foundation. The details of the Foundation's cooperation with the medical schools will be arranged by Colonel F. F. Russell. These activities are the result of special investigations made by the Foundation in Central Europe with respect to medical education. It has been found that a comparatively small number of medical schools serves a total population of seventy-five million people. With the single exception of Austria, all of the countries of the region under consideration suffer from a great shortage of physicians. There are reported to be less than 300 doctors in all Serbia. Outside of the Army medical officers, less than 2,000 physicians are available to care for the 25,000,000 inhabitants of Poland. Additional medical schools are needed adequately to serve these countries. In all of the universities of Central Europe the equipment (glassware, chemicals, apparatus, etc.) has been very largely used up during the four years of war and the two years of disorganized conditions and low exchange. The greatest desire for American and British medical journals was expressed at every university visited. Journals are furnished under an arrangement whereby the university pays in its national currency at the present rates of exchange, and the Foundaton makes up the difference due to loss in exchange. Belgrade has been selected as one of the strategic points in a world program in which a medical school must be established in the near future. The Foundation has decided to assist that project by lending a technical adviser in the organization of medical education, and Belgrade officials will be authorized to recommend to the Foundation from time to time as candidates for fellowships in specialized postgraduate medical study, persons who may be under appointment or consideration for appointment in the faculty of the proposed medical school in Belgrade.

Dr. John J. Kindred of Astoria, N. Y., was elected to Congress in November, one of the few democrats to escape from under the Republican landslide. In his previous term Dr. Kindred had an opportunity a number of times to speak and vote in support of public health and other measures relating to medicine, and he will, we doubt not, be equally active during the coming session in safeguarding medical interests.

Dr. Edward A. Park, associate professor of pediatrics at Johns Hopkins University, has accepted the invitation of Yale University, recently extended, to become professor of pediatrics in the Yale Medical School.

Aid for Paris Hospital.—A committee has been organized to raise funds for a new building for the American Hospital in Paris. This institution, now with a capacity of 32 beds, needs 100 beds, and a building fund of $400,000. Mrs. Robert Bacon, who made possible the American Ambulance Hospital in Paris during the war, is chairman of the committee. Among those serving on the committee are the following: Henry P. Davison, Dr. Joseph A. Blake, Dr. Alexander Lambert, Dr. C. C. Burlinghame, and Dr. J. P. Hutchinson.

Gift to Ogdensburg Hospital.—A. Barton Hepburn has made a gift of approximately $330,000 to the hospital in Ogdensburg bearing his name. The gift was made in connection with an appeal for funds to equip the nurses' home, recently provided by Mr. Hepburn.

Permanent Organization of Health Officers.—

On November 30 and December 1, last, a convention was held at Detroit which was attended by a number of health officers from the cities of the United States having a population of over 200,000. The principal object of this convention was to discuss the housing situation in the big cities and its effect on health. At this time resolutions were adopted and forwarded to the United States Senate Reconstruction Committee calling attention to the facts as found and petitioning the Committee for relief. A permanent organization of health officers, to meet in conjunction with the American Public Health Association was then established, with Dr. Royal S. Copeland, Health Commissioner of New York City, as chairman and Dr. H. Vaughan as secretary.

Positions for Roentgenologists.—The United States Civil Service Commission announces open competitive examinations for the positions of Roentgenologist, Associate Roentgenologist, Assistant Roentgenologist, and Junior Roentgenologist, and vacancies in positions requiring similar qualifications. The salaries of these positions range from $200 to $250 a month for roentgenologist to $70 to $90 a month or junior roentgenologist. In addition to salaries appointees will be allowed quarters and subsistence where possible. When these are not allowed salaries will be increased accordingly. Both men and women may enter the examination. The duties of a roentgenologist will be those of general roentgenological practice, including *x*-ray physics, technology, photography interpretation, and localization. The associate roentgenologists must be proficient in *x*-ray photography and posturing and trained in the ability to install, maintain, and repair *x*-ray apparatus; they must also be qualified for supervisory duty in a large laboratory, or as the head of a smaller laboratory. The qualifications for the assistant and junior roentgenologists are similar to those of the associate though to a lesser degree. The minimum requirements for eligibility for appointment to the position of roentgenologist are that the applicant shall have been graduated from a recognized medical college with the degree of M.D., and shall have had at least three years' experience in the subjects mentioned above. For the other positions applicants must have completed at least eight grades of common school or equivalent education and have received a certificate of proficiency from a recognized hospital, medical college, or technical institution in *x*-ray, physics, and technology. Applicants should apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C. Applications for permission to take any of these examinations will be received until April 5, 1921.

Obituary Notes.—DR. HYMAN CLIMENKO of New York, a specialist in neurological diseases, died at Mt. Sinai Hospital following an abdominal operation, on December 16, at the age of forty-six years. Dr. Climenko was graduated from the Long Island College Hospital in 1904, was a member of the American Medical Association and the New York Academy of Medicine. He was chief of the neurological clinic of Mt. Sinai Hospital, and attending neurologist at the Neurological Institute, the Beth Moses, Central Neurological, Beth David, Brownsville, and East New York Hospitals.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Nov. 27, 1920.

Clinical Characters of Influenza.—The annual report of the chief medical officer of the Ministry of Health is a perfect mine of information with regard to all matters related to preventive medicine. Influenza is notoriously a disease, the clinical character of which vary very considerably from time to time. Not only do different epidemics present certain clinical features at variance but the same epidemic appears to fluctuate in type. For instance, as the report points out, the figures of the American Metropolitan Life Insurance Company show that a distinct change in the character of the disease occurred in the beginning of February, 1920. During January of that year influenza in the United States differed essentially from that which prevailed in 1918. The total influenza and pneumonia rate was well within the normal. Another and more important point is the fact that the age distribution of the deaths from these diseases in January, 1920, did not all conform to the very peculiar age distribution in 1915. In that year the age distribution of deaths showed a high peak in early adult life. Of the deaths during January, 1920, the distribution conformed to that of pre-epidemic years, namely, a high peak in childhood and old age, and low points in early adult life. In February, however, a change occurred and the age incidence began to show a gradual approximation to the former type. A similar change was observed in Great Britain about the same time, although it may be noted that in some of the local epidemics the incidence in the early years of life was exceptionally high. But taking the figures for the country as a whole the age distribution approximated more nearly to that of the 1918 epidemic than to that which obtained in pre-epidemic years.

Cholera and the Risk of Its World Diffusion by Way of the Mecca Pilgrimage.—The pestilences that follow in the wake of war threaten to carry with them more fatal consequences than the war itself. The conditions in Russia and to a lesser extent in large parts of Central Europe, constitute a menace to the health of Western Europe. Typhus fever is being spread from Russia and unless its progress can be effectually checked may devastate the whole of Europe. But typhus is by no means the only ravaging disease, which from its home in Russia and in other parts of the Far East may sweep through Europe. Cholera is quite as greatly to be dreaded as typhus and the opportunities for its transmission from disease stricken Russia are not remote. As is pointed out in the report of the British Ministry of Health, the existing state of affairs in Russia are also of special importance so far as cholera is concerned. It has happened repeatedly that cholera having been introduced into Russia, has spread from there to other parts of Europe. It is needless to refer to several instances, but attention may be drawn to the fact that perhaps the most important starting point of the European epidemics, whether

arriving via Russia or otherwise, is the dispersal of pilgrims from the holy places of Arabia. At this annual pilgrimage there are gathered, or rather massed together in conditions highly favorable to the dissemination of water-borne infection, pilgrims from all parts of the Moslem world, a goodly proportion of whom come from eastern countries in which cholera is endemic. In fact, the adoption of the strictest precautions have long been an international affair. Before the war there had been for many years an increase in the number of pilgrims to Mecca. During the war the pilgrimage was almost entirely in abeyance, but on the conclusion of hostilities it increased and bids fair, if circumstances permit, to again attain enormous proportions. Moreover, railway facilities previously absent will provide opportunities for reaching Mecca. In short, it has become of the first importance after the war: (1) to secure that sufficient temporary provision has been made against the spread of cholera by the pilgrimage, and (2) to consider what more permanent and efficient arrangements will be required in future in consequence of altered political conditions. The British Foreign Office has taken action, but notwithstanding this the situation is beset with peril. Indeed, it is obvious that a Hedjaz infected by cholera during the pilgrim season demands concerted action arranged in advance at widely separated points in different territories. But it is equally obvious that any such action is difficult, almost impossible to secure so long as political conditions in Eastern Europe remain unsettled. It is hoped, however, that it will be facilitated by the proposals for coordinated action under the League of Nations, which has been embodied in the Turkish Peace Treaty. From every conceivable standpoint it is urgent that peace in Russia be brought about as soon as possible. The conditions in that vast country, which embraces within its confines many nationalities, and of which a large number of its inhabitants are of Oriental origin, and in parts of which cholera is endemic are a source of peril to the whole world. As a matter of fact so long as Russia is in a state of chaos, infectious diseases are liable at any time to spread like wild fire and perhaps destroy civilization. To prevent diseases spreading from Russia is eminently of international concern.

Should Doctors Dispense?—In Great Britain generally, and almost invariably in the country districts, the medical practitioner dispenses his prescriptions at his own office. It is the exception rather than the rule for a prescription to be dispensed by a druggist. Of course, this is against the interests of the pharmacists and they have been agitating recently for a repeal of this procedure. The Council of the Pharmaceutical Society is now endeavoring to obtain legislation to ensure the separation of the acts of prescribing and dispensing, leaving the ordering of medicine in the hands of the doctor, who should be precluded from making it up and giving the preparation of the medicine to the pharmaceutical chemist, who should not be allowed to prescribe or encroach upon the medical man's province in any way. The argument in favor of such a course is strong. Medical men know the therapeutical treatment required, while to the druggists trained in the chemical action and inter-action of drugs and in the technical methods of manipulating the same, is left the task of making up the medicine. Moreover, it is thought that legislation of this character would strike forcibly at two abuses. Dispensing in the hands of medical men is frequently not done in a consistent and thoroughly efficient manner. On the other hand, prescribing by druggists is not without its dangers. They cannot be expected to make a correct diagnosis, and it is certainly opposed to the welfare of the individual and the community that they should be allowed to do so. The rôle of the druggist should be sternly restricted to following out the doctor's instructions as to the manner of medicine to be given. And yet the legislation called for by the Council of the Pharmaceutical Society is open to a good deal of criticism, particularly from the medical standpoint, and it must not be forgotten that it would put the public to not a little inconvenience. Pharmaceutical chemists are not present in all districts, and thus it might and indeed would happen, that a medical man precluded from dispensing his prescriptions would be compelled to give a prescription to a patient who might have to go a considerable distance to obtain the medicine. The druggist, as a rule, does not live by pharmacy alone; in these days it often only forms a small part of his means of subsistence; he relies more for his profits upon a large assortment of wares and the position of his business abode is naturally dictated largely by this reason. Consequently, it cannot be expected that a pharmaceutical chemist should be always found within easy reach of a doctor. And lastly, there are some members of the public who would strongly prefer that the diagnosis of their condition should remain a secret between themselves and the doctor, as many prescriptions convey clearly to the druggist the nature of the disease from which they are suffering. There are many "pros" for the suggested legislation, but just as obviously there is a large number of "cons."

The Meeting of the General Medical Council.—The annual session of the General Medical Council opened on November 22 last. The address of the president, Sir Donald Macalister, was perhaps chiefly interesting because he dealt with a question that is exercising the minds both of members of the medical profession and of the general public. He referred to the Interim Reports of the Medical Consultative Councils for England and for Scotland, these reports have been discussed in previous letters. Sir Donald Macalister, who is shrewd and far seeing, expressed himself cautiously but favorably with regard to the suggestions contained in these documents. He thought that the proposals made therein were for the better organization of medical practice, the underlying object being to render more effective the manifold services which the profession of medicine in all its branches is capable of rendering to the nation. The reports have been sharply criticized from many quarters as being wholly idealistic and

utopian and it is therefore instructive to know what the president of the British General Medical Council thinks of the suggested scheme. While he did not bless it, neither did he condemn it. The scheme in its entirety cannot be carried out for years, if ever, but even its partial fruition signifies a considerable revolution of existing methods of medical practice, sympathy on the part of the public, and much financial aid from the treasury. Ideals come to pass sometimes, and if the health of the nation is to be bettered by the means suggested in the reports or by some of these means, they should be closely considered and discussed by the medical profession and the public.

Typhus Fever in Poland.—The Typhus Commission appointed by the Council of the League of Nations to study the sanitary conditions of Poland with special reference to the prevalence of typhus and cholera, made a report of its investigations to Committee No. 2 on November 24. The commission is of the opinion that the eradication of typhus in the areas of Poland, which are described in the report, is a question of international importance and recommend the League to render necessary assistance.

OUR LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, Nov. 15, 1920.

Public Hygiene in Switzerland.—In the present circumstances of unrest and otherwise, delays in the appearance of important documents are unavoidable. Such is the case of the Reports of the Federal Service of Public Hygiene of Switzerland for the year 1919, but, although tardy in its appearance, its contents possess considerable interest. Influenza, which developed in the spring of 1918, with still 104,612 cases in December of that year, fell to 32,023 in January, 22,730 in February, 16,126 in March, 7,825 in April, and 1,061 in May, 1919. From this time on only a few isolated cases have been reported. The total number of cases of influenza reported in 1919 was 86,056 as against 666,000 in 1918. But it is to be remembered that these figures do not exactly represent the reality, because many cases were not reported to the Federal Service. What is known of the clinical aspects and epidemiology of influenza might lead one to suspect periodical returns of the infection, as was the case in the pandemic of 1889-1890, which only became extinct in 1894, and the reappearance of an epidemic wave of the disease at the beginning of 1920 proved that this expectation was not unfulfilled, but it did not continue for any length of time. The Swiss Federal Council, in 1919, made medical declaration of influenza obligatory and this law is still in force, while on November 19, 1918, this body decided to subsidize the cantons and townships for expenses resulting from the extraordinary measures taken for controlling the epidemic. The total amount expended was 1,058,856 francs, and this total includes the sum of 46,270 francs for subsidies paid by the Swiss Confederation to cantons and townships for sums given to private individuals who had been deprived of their livelihood on account of closing certain establishments in which they were employed.

During 1919, hardly any smallpox was reported. There were two cases during July, one at St. Moritz, the other at Campocologno, both imported from Italy, where the disease was flourishing at the time. The expense of the town of Campocologno for carrying out the necessary measure for controlling the disease, in conformity with the Federal law of epidemics, amounted to 270 francs. Two cases of varicella reported from the canton of Zurich, and at first diagnosed as smallpox, led to the institution of prophylactic measures resulting in an expense of 586 francs. The diagnosis of another case reported from Neuchâtel remained doubtful. Since smallpox has offered a certain recrudescence in countries surrounding Switzerland for several years past, the Service of Public Hygiene has insisted upon vaccination, the only really efficacious means of prevention. The reason why there was no spread of the disease is, evidently, that in the canton of Grisons, where the two cases occurred, vaccination is obligatory, so that all the inhabitants had been rendered immune by this means.

Epidemic dysentery (bacillary dysentery) was and is still present in some of the countries surrounding Switzerland, and sporadic cases have been reported from the canton of Zurich (3), canton of Berne (4), the city of Basle (2), Schaffhouse (1), and St. Gall (1). There was also a slight epidemic in October, 1919, in the canton of Tessin in the region of Malcantone, with a total of twenty-eight cases with five deaths. In this epidemic it appears to be certain that the disease was imported from Italy and here, as in the epidemic at Ascona in 1918, the rapid and energetic intervention of the health authorities resulted in a speedy control of the epidemic focus.

Diphtheria showed a marked retrogression in 1919, so that it may, perhaps, be concluded that the end of a progressive increase of the disease for the past few years has been reached. The total number of cases in 1919 was 7,690 as against 8,566 in 1918.

The retrogression of epidemic cerebrospinal meningitis, already quite evident during the preceding years, was very manifest in 1919. Only thirty cases were reported—the same number as in 1913—while in 1918 there were eighty-one cases.

Typhoid fever is also on the wane—289 cases in 1919 as against 322 in 1918. This retrogression is the consequence of the measures taken in many townships for a better water supply. The Health Service was authorized to engage provisionally the services of two geologists attached to the Army Medical Service during the war, to study the question of potable water, especially in the regions where the troops were stationed. These two geologists are still at the disposal of cantonal and township authorities for any researches they may desire to have carried out in connection with the health authorities, chemists, and bacteriologists, and especially in the case of water supply. These together form the "Sanitary Survey Corps." By the results so far obtained this corps has fully justified its creation.

The other current transmissible diseases—scarlatina, whooping-cough, varicella, etc., have also shown a tendency to retrogress, measles alone showing a marked increase.

For many years malaria in an endemic form has disappeared from Switzerland, and in those countries bordering on it the hygienic measures adopted for its control had distinctly limited the propagation of the disease and had reduced in number the foci of paludism. But the war distinctly modified this condition and in many countries malaria has manifested a very marked recrudescence. It is particularly in armies in the field, especially those who fought in the Orient, that malaria is rampant, and these troops in their turn have contaminated the civil populations. It is certain that among the demobilized soldiers who have returned to Switzerland, there are many suffering from malaria. Given the difficulty of the diagnosis of chronic cases, it is undoubtedly a fact that those with paludal infection have been able to return to Switzerland without their condition having been suspected. A recent investigation made by the Service of Public Hygiene has shown that in many parts of Switzerland the type of mosquito, which is the vector of the infection, is to be found. The coexistence of these two factors, namely, the presence in the country of an increased number of malarial subjects and the relative frequency of the anopheles mosquito, has played the essential part in the diffusion of the disease and may, to a certain extent, result in the development of new foci of malaria. In reality, however, the danger is not great but, nevertheless, the Federal Council has made notification of malarial cases obligatory, in order that the health authorities may be immediately informed of their appearance and so be enabled to act at once.

The great exotic epidemics—cholera, plague, typhus fever—have so far spared Switzerland, but their presence in certain countries of Eastern Europe have caused the health authorities to be continually on the lookout in order that the Swiss frontiers may be properly provided with all necessary quarantine measures for suspected travelers.

3. Observations on the Significance of Functional Albuminuria in Young Men at Harvard University.—D. C. Parmenter found, from the examination of Harvard freshmen during four previous years, that 5 to 7 per cent. had albumin in the urine on a single examination. During the college year of 1919-20, 513 freshmen in Harvard University of an average age og 18 were examined. Forty, or approximately 8 per cent., showed albumin. Of these forty men six were excluded as having organic heart lesions which might account for their albuminuria. In the second examination, some weeks following, sixteen of these thirty-four still persisted in showing albumin. In the third examination two weeks later six of the thirty-four still showed albumin. This would seem to show that approximately 5 per cent. had a transitory albuminuria which may be designated as functional. This functional group comprises over 80 per cent. of the cases of albuminuria without organic disease. The writer considers it fair to say that a certain amount of evidence points toward postural causes for albuminuria. A small amount of evidence would seem to indicate that a certain amount of metabolic or nervous instability is also a predisposing cause. On the other hand, assuming that faulty posture or poor bodily mechanics is simply contemporary with albuminuria in the indication of subnormal physical efficiency and a nervous instability, and is not simply a cause of the albuminuria, if the appearance of albumin is merely one of a number of indications, no one of these indications would signify that a man should be barred from ordinary athletics. So far, his observations have shown that the athlete with albumin in his urine has only the transitory type. Perhaps, on the basis of the threshold hypothesis, he is not as efficient physically as the man without albumin. The man with the orthostatic type does not seem to feature as an athlete. Yet there seems to be no very good reason why he should not participate in athletics. Such a man, of course, should be watched closely. From the evidence so gathered the orthostatic albuminuria would not signify that he will be more subject to nephritis in late years since there seems to be some slight evidence of its tendency to decrease or disappear during the four years of the ordinary college curriculum. Hence it would seem justifiable to disregard the transitory type of albuminuria except as an index of physical ability during a definite time of life. The orthostatic type, on the other hand, while indicative of no physical deficiency serious enough to bar the individual from athletics, seems worthy of close observation.

4. Cutaneous Anthrax.—John Randolph Graham confines his discussion to the type of the disease known as cutaneous anthrax, or malignant pustule, having never seen a case of the internal variety, variously known as intestinal mycosis, woolsorters' disease, and splenic fever. He has had the privilege of inspecting, at some time during the duration of the attack, almost all the cases reported to the Health Department from the Borough of Manhattan since January, 1915; also occasional cases prior to that date. Under the head of treatment the writer advocates the method evolved about two years ago by Dr. Joseph C. Regan of the Kingston Avenue Hospital, Brooklyn. This scheme of treatment meets effectively the difficulties in cases where the inflammatory infiltration of the tissues is so widespread as to make operation out of the question, and is also applicable to any surface anthrax lesion. The cutting and destructive operations are discarded entirely, antianthrax serum being introduced directly into the body of the lesion itself by means of several small injections around the periphery of the eschar. Seven to ten cubic centimeters of the serum are used locally once daily, at the same time twenty to forty cubic centimeters are introduced intramuscularly, or intravenously, if the bacillus is found in the blood. At Bellevue Hospital, where this idea has been put into effect in a routine way, they have not been so conservative, for there they have used the serum intravenously in all cases, and have repeated the doses locally and in the vein every four hours for several days at a stretch, without, so far as the writer's knowledge goes, any serious or even especially unpleasant consequences. The results, though, have been no better

than at the Kingston Avenue Hospital. Practically all the cases this year have been treated by this method; furthermore, they have been as serious as any he has ever seen. Comparing the figures for the years covered by his experience, Graham believes that progress is being made toward a favorable solution of this problem.

5. Superficial and Deep Roentgen Dose Estimation.—William H. Meyer, being well cognizant of the fact that certain structures, both normal and pathological, show a pronounced radiosensibility, yet in connection with the absorption in one centimeter of flesh as measured in one millimeter of aluminum with present-day apparatus, considers the following conclusions justifiable: That a total cumulative absorption percentage of thirty-five or less is stimulative in action (increased metabolism). That a total cumulative absorption of plus fifty is mildly inhibitive in action to radiosensitive structures. That a total cumulative absorption of one hundred produces strong inhibition with retrogression. That a total cumulative absorption of plus two hundred is catabolic in action with retrogression and necrosis. That any of these effects may be produced at will within the first half centimeter depth of tissue. That as a rule only the first three reactions can be brought to bear below the first centimeter depth, without producing, at the same time, total skin destruction. Therefore, with widespread, deep-seated lesions, besides stimulation, an inhibitive dose is frequently all that can be hoped for. From these conclusions the writer wishes to go on record as stating, without reservation, that any superficial malignancy can be destroyed; and that with the early cases a far better cosmetic result can be obtained with radiant energy than with any other procedure, and this without pain or inconvenience, and frequently within one month following a single treatment; and that, when properly applied, recurrence within three years is rare. Therefore, any case of threatened superficial malignancy should receive the benefit of such procedure, and this in preference to the knife, caustics, freezing, or any other method, since his most difficult cases have been those subjected to previous interference. On the other hand, in few *bona fide* cases of deep-seated malignancy have the patients been reported as having been cured and remaining alive and well for a minimum period of three years.

3. The Roentgenology of Appendical Obliteration.—E. H. Skinner postulates that the filling of an appendix lumen in an adult at least thirty years of age with an opaque meal is sufficient to nominate such an appendix as the seat of chronic disease. The degree of such chronicity and the question as to whether such an appendix demands immediate or remote attention, and as to whether such an opaquely filled appendix is a cause of symptoms, are matters of shadow analysis, case history analysis, and the elimination of other lesions by differential roentgen and clinical analysis. From his study of the subject the writer is led to believe that the appendix is a functioning organ of lymphoid structure. It receives and expels colonic contents normally during childhood and adolescence. It proceeds to physiologic obliteration in adult life, this obliteration being normally accomplished at about the age of thirty. Opaque filling of the appendix is easily secured in childhood and adolescence by meal and enema. Appendical filling is a matter of sedimentation, widely patent os and antiperistalsis. The three operate in childhood and adolescence. Antiperistalsis filling is more apparent with increasing years, and is the essential element in the filling of appendices that are not obliterated after the age of thirty.

5. Vincent's Angina Infection.—Frank F. D. Reckford, from his study of the fifty-six cases which form the basis of this contribution formulates the following conclusions: (1) It seems to be definitely proved that the fusiform bacillus and the accompanying spirochete are one and the same, the latter being an evolutionary form of the former, but always present with the bacillus. (2) Vincent's angina is much more common than is at present realized, and that it is not recognized because of the failure to take a smear, and that furthermore it is frequently mistaken for diphtheria and syphilitic ulcers. (3) It is also probable that the considerable use of candy or proteins with the subsequent lack of oral cleanliness predisposes markedly to this infection; likewise, that poor teeth harbor the organism, and that it will manifest itself in its characteristic lesions whenever a suitable opportunity is given. It seems to be more frequent during the winter months. (4) The use of arsphenamin dissolved in glycerin is strongly advised in the treatment of Vincent's angina and infections in which the fusiform bacilli and spirochetes resembling Vincent's organism are found.

8. The Relative Usage of Narcotic Drugs in Hospital Service and Private Practice.—Thomas S. Blair bases this contribution on an elaborate statistical report rendered by the Bureau of Drug Control of Pennsylvania to the Commissioner of Health, and deals with the findings collected from the public hospitals of the State by experts in the field service of this bureau. This survey leads to the following recommendations: (1) There should be more and better rural hospitals. (2) Physicians whose training is defective should be aided to a higher standard of efficiency. (3) The importation and distribution of narcotic drugs for legitimate purposes should be under the care of a government bureau; but no government should, through subsidies, etc., participate in the profits of the opium business. (4) Proper limits should be placed on the amounts imported and distributed to physicians, pharmacists, and the like, reducing the amounts through a series of years, finally reaching the actual basis of need. (5) Smuggling of narcotics should be made an offense punishable by imprisonment for not less than five years, never by a mere fine. (6) The internal revenue taxation of narcotics and dealing therein, as established in the United States, should be kept up as a necessity in tracing importations, distribution, and usage. (7) Cannabis, hyoscyamus, hydrated chloral, and a few synthetic drugs should come under the narcotic-control laws, and no narcotic drugs whatsoever should be permitted in proprietary preparations and products sold without prescription. Exemptions lead to abuses. (8) Drug peddling in every shape and form should be sternly met with heavy jail sentences, never by the imposition of a mere fine. (9) The so-called ambulatory reduction treatment of drug addiction is rarely of any value, and should not be permitted under the laws designed to control addiction; but the drug addicts should, in some way, be hospitalized or humanely taken care of in proper institutions.

1. The Function of the Isolation Hospital in a General Scheme of Hospital Provision. A. K. Chalmers.

2. The Determination of the Basal Metabolic Rate, and Its Value in Diseases of the Thyroid Gland. C. M. Wilson, and Dorothy Wilson.
3. Some Points in the Diagnosis of Bilharzia Disease. F. G. Cawston.
4. Hidden Sepsis. A. White Robertson.
5. Operative Treatment of Umbilical and Ventral Hernia. Richard Warren.
6. Three Gastric Cases. R. P. Rowland.
7. Plague in Turkey During the War. F. G. Clemow.

1. The Function of the Isolation Hospital in a General Scheme of Hospital Provision.—A. K. Chalmers cites illustrative instances of epidemics outrunning isolation, and holds that it is not isolation that has failed, but that the knowledge of the causes of spread is as yet unable to supplement it by suitable action in other directions. Circumstances have compelled the displacement of epidemic hospitals from proximity to the teaching schools, and tended to restrict their functions to isolation and treatment. The increasing variety of diseases already being treated in them makes the development of clinical research a necessary addition to these. In the interest alike of the community, the State, and the training of future practitioners of medicine, it seems desirable to contemplate a time when the epidemic hospital will become an institute of research applied toward the elucidation of the problems with which infectious disease is surrounded.

2. The Determination of the Basal Metabolic Rate, and Its Value in Diseases of the Thyroid Gland.—C. M. and Dorothy Wilson state that basal metabolic-rate determinations have been found amply to justify the time spent upon them in cases of impairment of function of the thyroid gland. They mark off toxic from non-toxic goiter, establish or refute suspicions of hypo- or hyper-thyroidism, and furnish a graphic record of the results that follow the treatment of these conditions, so that the selection of the line of treatment becomes less capricious and comes to rest upon exact methods. Moreover, some of the writers' observations suggest that these determinations will be found to have an altogether wider and more important application in general metabolic disorders, particularly where the balance of function between the different glands of internal secretion is impaired. In this communication, however, it is their purpose to draw the attention of clinicians to the importance of these determinations, especially in cases of disease of the thyroid gland, and to set forth very briefly the methods used in the test.

4. Hidden Sepsis.—A. White Robertson emphasizes the point that since the war old-time insular immunity against amebic, protozoal, and malarial infections no longer pertains. The well-informed practitioner of to-day, therefore, must be prepared to recognize at any moment in his practice one or other of these legacies of an empire at war. So shall "pyrexias of unknown origin" disappear from statistics, and "hidden sepsis" be revealed.

5. Recent Advances in Surgical Treatment of Cancer of the Rectum. J. P. Lockhart-Mummery.

1. Treatment of Subacute Nephritis by Kidney Decapsulation.—Sir Thomas Horder briefly reviews the history of kidney decapsulation and reports four cases treated by this procedure. Consideration of these four cases, together with careful analysis of all the available records, led him to the conclusion that there is a clinical type of nephritis in which—when thorough general measures have proved unavailing, and a reasonable time element, during which it is known that resolution not infrequently occurs, has passed—decapsulation becomes a definite indication and promises satisfactory results. This type is termed—not inappropriately, in his opinion—*subacute nephritis*, and is characterized by extensive and considerable edema, massive albuminuria with casts in the urine, toxic symptoms of the chronic uremic kind, and an absence, or the presence in only slight degree, of cardiovascular changes (arterio-capillary fibrosis, hypertrophy of the left ventricle, arterial hypertension and retinal degeneration). This was the state of things in both his cases that resolved completely after the operation. In the two cases in which some definite improvement followed the procedure, but no cure, definite evidence of cardiovascular changes was present, and the type of disease suggested a general involvement of the arterial system rather than a local inflammatory process in the kidney. This consideration confirms the general idea that subacute nephritis is a different disease altogether from generalized arterio-capillary fibrosis, as a part of which process the kidney vessels suffer early, and the kidney substance suffers secondarily to the disease in the vessels. In subacute nephritis the causative agent may be regarded as either past and over, or, if still present, it may be regarded as producing its effects primarily upon the kidney parenchyma; in chronic interstitial nephritis, granular kidney, and (or) the arterio-sclerotic kidney, the causative agent may be regarded as operating chiefly upon the whole arterio-capillary system, including the kidney glomeruli. Concerning the mechanism by which the results of decapsulation are brought about, the writer declares he has little or nothing to say of actual fact. It is generally thought that depriving a kidney of its capsule, and thus bringing the cortex into close contact with the perinephric tissues, leads to the formation of new vessels which anastomose with those of the kidney itself, thus providing for the removal of inflammatory exudates and assisting in reestablishing renal function. He regards this process of formation of new vessels as actually taking place. But a difficulty is encountered: The good effects of decapsulation are immediate. whereas this new system of vessels must necessarily take time to form. Are these rapid effects due to the relief of tension? This can scarcely be so, since, apart from cases of acute nephritis little or no actual tension is seen to be present at the time of the operation. The question must remain for the time unanswered—unless it be an answer to say that the mechanism of production of the diuresis and disappearance of edema and of symptoms generally is of the same kind as in the process of "wet cupping." Very little is known about the exact relation which the perenephric tissue bears to the capsule of the kidney and to the kidney proper. Actual observations and experimental work are as yet very slight. The whole subject calls for systematic study. Such a study may well be found to supply the answer to the question as to the mechanism by which the good results of decapsulation are produced.

5. Recent Advances in Surgical Treatment of Cancer of the Rectum.—J. P. Lockhart-Mummery emphasizes the following points: (1) The anus is sealed up before the operation field is prepared. (2) The rectum is freed from in front and from the perineum afterwards. (3) The peritoneum is opened from the front of the rectum. (4) The bowel is divided with a cautery between clamps, and the end invaginated. (5) The wound is closed without drainage.

Encephalitis Lethargica in Holland.—According to Cramer, the grippe epidemic which still existed in Holland during the period April-August, 1919, but in a vanishing stage, was attended by cases of the new sleeping malady reported among others by Beck, van Wijhe, van Heukelum, Bosman, and van der Tak. Apparently no one thought otherwise than of a cerebral localization of influence. One spoke of encephalitis gripposa and cerebral grippe. It was thought that the influenza was returning in a new wave. The author has recently seen in Utrecht a typical case of sleeping sickness which was not associated with influenza and which, studied in great detail, shows a distinct behavior throughout. He next compares his case critically with those seen during 1918 and 1919 and concludes that the type is the same. Attention is called to grippal encephalitis seen in cases of grippe pneumonia as an entity which differs from primary encephalitis. The author does not attempt to evade the conclusion that sleeping sickness may be a parainfluenza—a special form due to a neurotropic strain of the grippe virus.—*Nederlansch Tijdschrift voor Geneeskunde.*

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DISTRICT BRANCH.

Fourteenth Annual Meeting, Held in Poughkeepsie, N. Y., October 21, 1920.

THE PRESIDENT, DR. JOSEPH B. HULETT OF MIDDLETOWN, IN THE CHAIR.

Report of a Case of Myxedema.—Dr. DANIEL B. HARDENBERGH of Middletown, N. Y., read this paper. (See p. 1054)

Dr. CHARLES I. REDFIELD of Middletown stated that a member of his family had been under treatment for myxedema for sixteen years, and it had been very interesting to follow her case. Recently she had had a severe and complete breakdown, involving the heart and kidneys. Apparently she had had angina abdominalis and angina pectoris. In addition to the cardiac disturbance she had an acute parenchymatous nephritis. After a time, on small doses of thyroid, she had begun to recover her strength. It was thought fourteen years ago, from the symptoms presented, that she had Bright's disease. There was no cure for hypothyroidism; nothing could be done except to administer thyroid, which did not cure, but kept the symptoms down. When thyroid was taken it was observed that there was a leaking from the mucous membranes, and when it was stopped there was a choking up, because of the edema, and it was this edema which often led to mistaking the condition for Bright's disease. Dr. Hardenbergh had spoken of the slowness of the mental processes in his patient. In the case of the speaker's relative there had been some slowness of speech, but no loss of memory, and the mental processes were bright.

Dr. HENRY LYLE WINTER of Cornwall said he had begun to employ the thyroid treatment in the neurological clinic of the old New York University about 1894, and he had followed it along for a number of years. There was a great difference in thyroid preparations, and, in his experience, the English preparations were much better than the American. The theory advanced to account for this fact was that the English obtained the glands for the preparation from sheep and not lambs. Six or seven months ago he had seen a case in crisis. The heart condition demanded immediate relief. He tried suprarenal extract given hypodermically, on the theory that with disturbance of one endocrine gland other endocrine glands would also be disturbed. The result of the suprarenal extract on the heart action was very satisfactory. The heart recovered its tone and rhythm in about twenty-four hours after the administration of the suprarenal extract. He had used it in only this one case, and hence did not know how it would act if given regularly in such conditions, but apparently it met the requirements in this instance.

Dr. JAMES E. SADLIER of Poughkeepsie said he thought this society was to be congratulated on having a paper so germane to the present studies on the endocrine system, for most of us were becoming alive to the situation and realized that we must look to the endocrine system for a vast amount of explanation of things inexplicable in times past. It was well to emphasize the fact that the variations between hyper-, hypo-, and normally functioning ductless glands must be recognized. The surgeon would have to recognize these differences in operative procedures upon the glands. For example, if a young girl came into puberty, with enlargement of the thyroid which caused anxiety to her parents so that they brought her to the physician for advice, it was important that the physician recognize that this was a physiological process; that the thyroid was a sex gland, and that the secretion of that gland was necessary for the proper performance of physiological sex function. It was almost a weekly occurrence to see glands of that kind, which should not have been removed, subjected to surgery. The enlargement of the gland and hyperacidity were a part of normal development at that time, and if such a gland was disturbed by surgery it might lead to a condition such as Dr. Hardenbergh had described. If one observed that type of case which did not have the normal physiological enlargement of the thyroid at puberty he usually found that those cases were amenorrheic or dysmenorrheic. The dysmenorrhea would frequently be relieved. These patients were given thyroid substance together with ovarian extract. With regard to the actually pathological thyroids in hyperthyroidism or exophthalmic goiter so-called, frequently after operation there would be an enlargement of the portion of lobe left in situ, and in such instances one should be very careful how he became excited over what was a physiological enlargement of the portion of the gland remaining. This was probably Nature's effort to produce the proper amount of function. If this enlargement became excessive, leading to operation, one should be very careful how much of the gland he removed, lest he throw the patient into a condition of hypothyroidism which was worse than hyperthyroidism. The question of operation for hyperthyroidism required well balanced judgment to avoid substituting for one pathological condition another which was worse.

Dr. LOUIS V. WALDRON of Yonkers had observed a case of hypothyroidism which followed the description of Dr. Hardenbergh's case except with reference to the dryness of the skin. In his case thyroid treatment had no effect whatever. He finally took the patient to Dr. S. W. Lambert, who asked if the urine analysis had shown the presence of sugar. There was no sugar in the urine, but there was sugar in the blood. This was mentioned to point out the importance of watching for hyperthyroidism as well as for diabetes when sugar was found in the blood.

Dr. HARDENBERGH, in closing, said that the only indication of any trouble with the tonsils in the case cited was the history that in early youth the tonsils were enlarged. Following this observation there was hyperthyroidism. If one held the theory that infected tonsils infected the thyroid, he might find something in this case to support that theory. The patient, however, had not had recurrent attacks of tonsillitis. He agreed with Dr. Winter that the English preparation of thyroid extract was the best. At one time the patient had shifted to another preparation and this was followed by urticaria, which he thought might have been due to ptomaines in the extract of thyroid. The dosage advised was rather misleading. He felt sure that if he had started with three tablets daily he would have had trouble. It was probably safer to start with less than the dose advocated in the directions for the use of these tablets.

President's Address.—Dr. JOSEPH B. HULETT of Middletown delivered this informal address, in which he said the war had shown that America, or the United States, was the greatest country in the world. We had become the greatest country in the world in much less time than had some other countries. There must be some reason for this. The reason was that each man was allowed to work out his own destiny. The Constitution of the United States granted to every man the right to be the shaper of his own destiny. Of late years we seemed to be drifting toward one-man rule. That system seemed to be a failure, as was shown by the downfall of Kaiser Wilhelm, the Czar of Russia, and some others. The world had been drifting toward socialism, and one could see the way that had worked out in Russia. That, too, seemed to be a failure. It would also seem that political rule was a failure. The downfall of Rome represented that. He believed we should not follow after old world failures. The old country plan was to have someone rule someone else. Allowing each man to work out his own destiny developed the qualities of independence and of leadership. During the war the German soldier, if left without a leader, was at a loss what to do, and fell down, but our men, when deprived of their leader, went right on of their own initiative. In the medical world the same principle held good. He believed the medical profession should not be ruled by someone else. They had come very near, at times, to being ruled by politics. That had always come to him as a surprise, because when he joined the medical profession he thought he was joining an independent profession which always would be independent.

The Medical Society of the State of New York was the governing body of the medical profession in the State of New York. He saw no reason why they should turn themselves over to the State. As we had come to be the leading medical men of the world under a government which allowed each man to work out his own destiny, why turn around and adopt an old world failure? The poor in this country, through the gratuitous services of the medical profession, were looked after as well as any in the world. There was no question that owing to the willingness of the profession to give their services they had been imposed upon and were treating many who were not entitled to charity. This was more especially true of New York City, of Buffalo, and of other large cities. The profession should look into such abuses. To-day a physician had no one to interfere with his practice or to tell him whom he should treat, and we should see to it that we did not sell out to any politicians. We should look after the general practitioner and the new men coming into the profession. The doctor who said he was a specialist should prove it by his work. He did not believe in allowing any board of supervisors to say who were specialists. He would like nothing better than to go down to posterity as having helped the rank and file of the profession. We should be originators; if there were certain things to be done we should do them ourselves. He did not believe we should be told by the politicians what branch of medicine we should take up. We should say that we would handle the medical profession as we believed it was our right to do.

The Future Physician.—Dr. RICHARD R. KEVIN of Brooklyn, president of the Medical Society of the State of New York, delivered this address, in which he said, in part, that the Medical Society of the State of New York was great in proportion as its units were great, and as the individual members thrived, so would the society thrive. He congratulated them because they had been good diagnosticians in this section of the State in that they had elected as president a man who would make his influence felt in the councils of the society. He could speak for the future for he had sat on the benches beside that man when he was a student. In those early times one could have prophesied his future, and he had always made good.

In order to determine what should be the attributes and functions of the future physician, present conditions and environments which had set the present physician on his pedestal must be reviewed. Unlike the law of gravity, economic conditions changed, and all such changes came about through evolution and not revolution. The physician had gone through a process of evolution and standardization since the time when the barber was the surgeon. Just as the achievements of medicine and surgery had advanced, so the State had required higher and higher qualifications of those who practised medicine and surgery. To-day practically all medical colleges required two years of college work before matriculation, and four full years in a recognized medical college and an interneship in a recognized hospital were required before a license to practice medicine was granted. Thus one could see how the State had advanced in its requirements. The late Dr. John B. Murphy expressed the fear that excessive standardization would suppress individuality and dwarf genius, and would result in a sudden decrease of original medical talent. It had been said that superior endowment in intelligence, ingenuity, and well-balanced judgment were necessary to progress. The question of the standardization and qualifications of the present and future physician was too large to discuss at present. Assuming that the requirements and qualifications of the future physician would not have changed, what were the prospects for the future physician? Would he be permitted to pursue his profession unmolested or would he encounter public health legislation and State legislation? Physicians in the past had been leaders in matters of public health. If he read correctly the new economic conditions, they were bringing to the front social welfare. This being so, he could see a change in the curriculum of the future physician. Certainly his function would be to conserve the health of the well, to arrest incipient disease, to care for chronic cases, and to bring comfort to the old. In preventive medicine the sanitary engineer and the social worker had entered the field. When one considered that at this advanced age we had failed to suppress scarlet fever, whooping cough, poliomyelitis, and many other infectious diseases, one could predict that there would be greater advancement so far as preventive medicine was concerned. In the future he saw abundant specialization, but towering over all he predicted that the family physician would have come back to his own. Children would be better cared for. There would be frequent examinations, mental as well as physical. The general health would be cared for and special defects corrected. They would have better men and women in the future. The future physician would have acquired ample knowledge in hygiene and eugenics. The public would be educated to frequent physical examinations, and the physician would achieve better results in the treatment of the sick. These improved results would not be due to a change in the mode of treatment, but rather to the doctor obtaining the patient in the incipient stage of disease. The future physician would dominate the diagnostic clinic. The pathologist, the roentgenologist, the laboratory worker, and the specialist in every line would contribute their part, but the physician would correlate the information that they brought to him and pass final judgment. In the final analysis, the future physician was already here in his prenatal state. What were we going to do to remove the obstacles that encumbered his path? We should educate the public now to their relation to the new physician. This was a problem which they should study. They should see to it that the new physician was provided with the opportunity that would make his work a delight and a pleasure and his life a blessing to mankind.

Unappreciated Agencies in the Defective Development of Children.—Dr. CHARLES GILMORE KERLEY of New York made this presentation, in which he asserted that at the age of seven years the boy was seven-tenths a man and the girl seven-tenths a woman. If errors of development from whatever cause had preceded this period they would never be entirely eradicated. Evidences of this were apparent in the physicial condition of those who had grown up on the Continent during the late international war. Dr. Kerley said he would not make an attempt to cover all that related to right development, but would merely call attention to certain factors which had an important bearing on this subject, and which were generally unappreciated. Among these was defective breast feeding. It was a very usual error to believe that breast feeding was always efficient and the best means of nourishment. Breast feeding might supply substance entirely inadequate to the demands of the infant. Because good breast milk was superior to all other forms of food did not mean that inferior breast milk might not be much less desirable than suitable substitute foods. Breast milk was a commodity, and there were varieties of breast milk as well as of other commodities. Each year he saw a goodly number of cases of malnutrition in infants six months to one year of age fed exclusively on breast milk. These infants were underweight in some instances, but the most usual evidence of defective nutrition would show itself in flabby muscles, secondary anemia, and beginning rachitis. A considerable number of nursing women could supply the child adequately until the completion of the fifth month, fewer could supply him adequately until the completion of the seventh month. After this period practically all breast babies in New York should have the advantage of additional feeding. Breast milk should be repeatedly examined as to quantity and quality during the nursing period. Another mistake to which Dr. Kerley called attention was the excessive use of cow's milk in older children. After the eighteenth month in the average child better growth would result with a reduction of the daily milk allowance to approximately twenty ounces daily, provided adequate nourishment could otherwise be furnished. When other foods could not be given in suitable amounts, a large daily milk content in the diet might be of advantage to balance a defective dietary. He had seen a vast number of super-milk fed children with varying degrees of malnutrition who were taking from one to two quarts of milk daily. Almost invariably they had a capricious

appetite, and disliked other articles of diet, largely because they were never given an opportunity to become really hungry, and to become acquainted with a wider range of foods. Physically they showed poor muscular development, were pot-bellied, constipated, underweight, and flabby. They were subject to frequent so-called bilious attacks. Blood examination seldom failed to show secondary anemia. Mentally they were irritable and difficult of management. Nature had fashioned the child for other foods than milk, after the cessation of the nursing period. Always the quart of milk was bad teaching. Cases of persistent anemia in young children—children with a hemoglobin content under 30 per cent., and with red cells varying from 1,500,000 to 2,500,000—treated along the usual lines of diet, with arsenic and iron, made little progress. These were not simply cases of malnutrition with anemia; they were cases of anemia with secondary malnutrition, and were often seen in quite young infants. The management which he had found rapidly successful in these cases was intravenous blood transfusion, 120 to 150 c.c. of human blood from an appropriate donor. Excessive activity which meant overwork contributed its quota to the hoards of poorly developed children. The child who awakened early and was busy all day in childish activities until seven or eight o'clock at night would not thrive as well as if there was reasonable restraint and a mid-day rest after the mid-day meal. He attempted to cultivate indolence in such natures. A considerable number of children came to him because of inadequate growth, who had been subject to frequent illness. When a child was ill development was delayed. Several illnesses during the year would leave an appreciable mark upon the child. Abnormalities in the gastrointestinal tract constituted another factor in certain cases of malnutrition. He had found it necessary in about eighty cases of tardy malnutrition to make *x*-ray studies of the gastrointestinal tract. In the child with the persistently poor appetite, who had to be coaxed or forced to eat, the explanation was found in pylorospasm, in dilated stomach, and in ptotic stomach. He had frequently found food residue in the abnormal stomach from six to ten hours after a bismuth meal. A child would not be hungry with food residue in the stomach. In addition to defective food intake these children were the losers in that they were those who had frequent attacks of recurrent illness in the nature of vomiting, and fever, the entire illness covering perhaps from five to seven days. In children with persistent malnutrition the explanation would sometimes be found further on in the digestive tract, in the dilated cecum, with ptotic or dilated colon, in angulations, in the enlarged and elongated sigmoid. The last was one of the most frequent causes of obstinate constipation and a low degree of toxemia, and of recurrent vomiting. He would not undertake the care of a habitual malnutrition in a runabout child without an *x*-ray of the gastrointestinal tract. Dr. Kerley exhibited a number of lantern slides illustrating these various anatomical abnormalities of the gastrointestinal tract.

Dr. JAMES E. SADLIER of Poughkeepsie said he wished to make one remark in reference to Dr. Kerley's paper. In the slides Dr. Kerley had shown several of the pictures which showed retention were labeled pylorospasm. Pylorospasm was not a disease, but a symptom; it was no more a disease than acidosis was a disease. The question was what was the underlying factor in those cases? Was it the result of a pathological condition in some other portion of the abdomen? It had been found that pylorospasm was only the firebox on the corner, so to speak, giving the alarm for a neighborhood conflagration; in other words, it was merely a symptom. As to the enlarged sigmoid, the question here was whether there was a spasm of the rectosigmoid which held back the fecal current, which was the cause of Hirschsprung's disease, or megacolon. In other words, were one or two of the illustrations Dr. Kerley had shown illustrations of modified Hirschsprung's disease?

Dr. JOHN A. CARD of Poughkeepsie said some of these cases were cases of purely mechanical obstruction, others had been pathological obstruction. Dr. Kerley had shown the plates merely to bring out the fact that in a great many children who appeared with malnutrition it could be traced to an anatomical condition in the stomach or intestines. The slides were not so much to show the mechanical condition as to show how frequently these conditions might be the cause of malnutrition.

Syphilis of the Nervous System in Children.—Dr. EDWARD LIVINGSTON HUNT of New York presented this paper, with the object of calling attention to some of the manifestations of syphilis of the nervous system in children and of illustrating them by a few cases. It was first necessary to consider in what respects congenital and acquired syphilis differed, as most syphilis in children was congenital. In congenital syphilis more tissues were involved and the involvement was more complete than in acquired syphilis. Apparently fetal tissue displayed very feeble resistance to syphilitic invasion. This resulted in the nervous system being involved more frequently and earlier than in later life. One would expect the same train of symptoms in the two types, and in fact they were similar, but there were certain variations and differences. In the congenital type the signs of involvement of the brain were more frequent than signs of involvement of the spinal cord. As a result mental symptoms, paralyses and optic atrophy were seen, whereas in acquired syphilis one found ataxia, etc. In the congenital syphilis the nervous symptoms, while they might manifest themselves in almost any form, were more apt to be of the meningeal type. The pathological changes were practically the same in the congenital as in the acquired manifestations; the same structures were affected and in the same way. In the congenital type the clinical signs pointed to a more general involvement than in the acquired type. The more one studied the congenital type the more thoroughly was he convinced that the nervous system became involved at an early date. Dr. Hunt described the characteristics of the congenital syphilis, and stated that Hutchinson's teeth were not as common as was taught. Few teeth were apt to be involved rather than many. A case which illustrated some of the points was a boy of 12 years, with a large head, immobile pupils, saddle nose, poor control over sphincters, and mental retardation. His blood Wassermann was four plus, the spinal fluid was also positive, as was the colloidal gold test and the luetic curve. The symptoms of syphilis of the nervous system might vary from restlessness, sleeplessness, enuresis, and slight mental deficiency to amentia. The colloidal gold test was the most delicate of all the tests. Lumbar puncture became an essential part of examination in every case of suspected syphilis, in every case in which syphilis was hereditary, and in every case characterized by nervousness, backwardness, and mental deficiency. Too much emphasis should not be put on a negative Wassermann, and none at all in those cases in which the spinal fluid gave a positive colloidal gold reaction. An illustrative case of nervous syphilis in a child was that of an infant admitted to St. Luke's Hospital last March, when one year old. The child had never assimilated food well, lost weight, never sat up straight, never had full control over his sphincters, had snuffles since birth, was rachitic, had an enlarged head and wide open fontanel, and was pot-bellied. The *x*-ray showed involvement of the left lung. There was marked enlargement of the epiphyses. The red blood cells were 2,800,000, hemoglobin 36 per cent. There was a four plus Wassermann and a positive colloidal gold test. Salvarsan was given hypodermatically. The child died a few weeks after admission to the hospital. In juvenile paresis convulsions usually appeared early. The average age at which juvenile paresis was met with was twelve years. The juvenile paretic was more likely to have convulsions than the paretic adult. The presence of juvenile paresis in a family placed upon the physician the duty of examining and testing every member of the family. In paresis in the adult it was usual to find a gain in weight, but in paresis in children there was as a rule a loss of weight, and one of the most frequent symptoms was slow and incoherent speech. Juvenile tabes was more rare than juvenile paresis, which was accounted for by the complexity of juvenile syphilis, and the fact that it affected the brain rather than the spinal cord. The average age of the appearance of juvenile tabes was

fifteen years. Pure spinal syphilis was almost unknown in congenital syphilis. The fetal brain tissue was probably more susceptible than the tissue of the spinal cord. Hydrocephalus was frequent. The eighth cranial nerve was most frequently involved, which might be due to its extensive ramifications, and its susceptibility to toxemia. In children showing mental backwardness, mental deficiency, and pure nervousness, lumbar puncture should be made and the gold test carried out. The prognosis in congenital syphilis was worse than in the acquired type, which was accounted for by the very extensive involvement and the underlying developmental defects. The age at which congenital syphilis of the nervous system might develop varied greatly. It might be at any time up to the sixteenth year. The precipitating cause was sometimes found in infectious disease. Treatment was not promising. Stigmata were not necessarily present.

Dr. MORRIS STARK said Dr. Kerley had given a very good example of the old adage, "As the twig is bent so the tree is inclined." As the early development, so was the health in later life. The newer thought regarding the effect of the essential food substances on growth was that not only were carbohydrates, proteins, and fats and inorganic salts required, but that the vitamines were also essential. When he had found a child who did not come up to the standard as regards growth and development, and there was no other pathology to account for the condition, he had noted that these accessory substances, the vitamines, had been overlooked. It was due to a lack of these accessory substances that the mother's milk was not always a suitable food. Funk and others had brought up the question as to whether the mother was getting sufficient vitamines, and whether, when the child was not thriving on the mother's milk, it might not be due to a deficiency of these accessory substances.

The chemical analysis of milk might seem to show that it was perfect in composition, and yet it might not be a perfect food, so it was necessary to investigate further, not only by looking for the outspoken signs of metabolic deficiency or for hidden ones, and when irregularities were discovered not explained on physical or chemical grounds, the child should be fed these accessory substances. Then if the mother's milk was deficient in these substances and they had been supplied in other ways the child would thrive. Dr. Hess had shown that tomato, also, as well as orange and potato, would supply the additional vitamines, and if these or other fresh vegetables were added to a pure milk and cereal diet the child would thrive even if these foods represented very few extra calories. Much experimental work had been carried on showing that cow's milk did not contain the same amount of vitamines in the winter that it did in the summer when the cows were in pasture, and that children fed on cow's milk in the summer were not so liable to develop rickets as those fed on cow's milk in the winter. This showed that if one fed cow's milk under certain conditions it might be necessary to add other articles of diet to supply additional vitamines at times without increasing the caloric value of the food. The question of lunch hour for children also determined how they thrived. Dr. Stark advised just a bite at the school lunch hour, and then a hearty meal when the child came home from school in the afternoon and had more time to eat properly. The determining factor in the proper growth, development, and health of the child was entirely dependent upon early recognition not only of hygienic shortcomings in the child's environment but also lack of proper maagement of the diet in the light of modern knowledge, and that very early in the child's life.

Dr. HENRY LYLE WINTER of Cornwall said Dr. Hunt had brought out a number of conditions in connection with the manifestations of congenital syphilis which were most important and which were likely to be overlooked. In his experience, unless a child was known to have inherited syphilis, the family physician was very likely to pass over some points and not to consider the possibility of syphilis. The absence of stigmata was the rule, and their presence the exception. One of these points was that of epileptic seizures in congenital syphilis. He felt that every child who, before puberty, developed recurring convulsions, was under suspicion of having hereditary syphilis. In all such cases the Wassermann test should be made on the blood and spinal fluid. He cited two such cases, one treated intramuscularly, and the other intravenously, with salvarsan, which apparently recovered. Convulsions coming on repeatedly in young children were always suggestive of a possible specific origin.

Dr. LEWIS M. SILVER of New York said he just happened to have under observation a case that was interesting in this connection. In 1900 he had delivered a baby and at the time of birth there were absolutely no symptoms that would excite suspicion of syphilitic infection. He had been seeing the family during all these twenty years. Only recently the mother had brought her son to him because he was beginning to stammer and was mentally retarded. He sent the lad to a class for the correction of speech defects. That was last spring. Recently he had noticed the patient had fixity of the pupils and that the right pupil was more dilated than the left. He then went back over his books and found that when the boy was six weeks old the mother had brought the child to him and that a diagnosis of hereditary syphilis had been made. The Wassermann test was unknown at that time, so the child was treated with calomel tablets in the usual way. There were absolutely no stigmata of syphilis in all the twenty years, and no one would have thought of syphilis at the present time had it not been for that diagnosis in 1900. The Wassermann test was made and found to be strongly four plus. A spinal fluid examination gave a positive reaction in all four particulars. The boy was sent to a well-known syphilographer, who confirmed the diagnosis of neurosyphilis. The involvement of the deep reflexes, the pupillary reaction, and the mental retardation was the result of neurosyphilis. Before the father was married he had been treated for gonorrhea, but repeated Wassermann tests were negative. Now the mother was being tested and later found negative. The interest in this case was the long period during which there were no manifestations of hereditary syphilis—twenty years. He had understood Dr. Hunt to say that twelve to sixteen years was the average age at which children showed these late manifestations of neurosyphilis. He was not willing to entertain the thought of an acquired syphilis in this case.

Health Center Bill.—Dr. C. C. DURYEE of Schenectady discussed this subject. After commending the vision of the future concerning the physician, as given by the president of the State Society, he said all were aware that changes were going on in the profession. The day of opinion was disappearing, and no longer could a man called in to see a case say "in my opinion this is this or that kind of a case." He must present some reason for his opinion. In other words, the medical profession had been growing rapidly out of the condition of practising simply an art, into that of practising scientific medicine. This change had not been completed, but it was in the process of evolution. In order to carry out scientific medicine certain things were necessary. The bill introduced into the Senate by Senator Sage, known as the Health Center Bill, was drawn up by physicians, and aimed to provide certain of these things. No attempt had been made to have it pass the Legislature. It had been sent back to committee time and time again for amendment, and had been sent to physicians throughout the State in order that it might be made to conform to all reasonable demands of the medical profession. But to return to scientific medicine, since some of the early experiences with this bill directed attention to it; he had lived only sixteen miles from the Legislature and had sometimes visited it, and he had never yet known of a bill being presented which influenced or concerned the medical profession that any medical men had handed in. Medical men might come to a hearing on a bill affecting their interests, but at these hearings the shortage of regular medical men was notable; this shortage was made up by a lot of men they did not recognize, some of whom were licensed and permitted to practise medicine in this State. He had never known of a bill drawn by doctors in the interest of the general public and presented to doctors for their approval, with the exception of the Health Center Bill. One objection advanced

against this bill was that it was State medicine and was offering charity to the people. Was there anybody who had found any great difficulty or hesitancy in receiving State aid in education? The only complaint one heard in this connection was that some fund was too little. There was at present a tremendous pressure on hospitals and laboratories to meet the demands made upon them. Why should they not be relieved by decent State assistance? Was it not the duty of the Legislature to provide for health and for the highest standard of health and well-being of the residents of the State? Was State aid not equally as applicable to medicine as to education? There were some laboratories doing public health work but they were not doing the amount of work necessary to give physicians the aid they needed in examining cases It was quite true that in some localities physicians had to depend for urine analysis on the methods of forty years ago and had no means of getting the information that could be furnished by modern diagnostic methods. They had no means of determining the functional capacity of the kidney by the phthalein test, and no way of having a blood examination. Would it not be wise to secure this service for hospitals and for physicians? It would come to the people just as money was given to the educational department by direction and allotment of a commission. There was nothing to cause them to feel that it was a danger to the profession. It was possible that such a law would be of little use in a place like Poughkeepsie, and for that reason the bill was permissive and not mandatory. Hospitals were no longer used merely for the sick, but as places for diagnosis. He believed there were many places where this bill would fit, and there were places where it might not be needed; so in considering the bill he hoped no one would think merely of his own immediate environment, but would remember that the State of New York had many and divers localities. The general practitioner of the old school had developed his skill and self-reliance to an extent that the city physician never acquired, and it could not be said that he was not doing the best he could for the people, but that he should be supplied with tools that would enable him to do even better work. Dr. Duryee said he was a believer in clinical diagnosis, and he did not believe one should rely upon the laboratory altogether. In rural localities the physician should have the laboratory facilities that the city physician had. Dr. Kevin had drawn a picture of group medicine where each of the various experts made his special investigation, the general practitioner coordinating the results and making the résumé. That was not a vision of the future; it was here just now. Dr. Duryee said he was expressing only his own opinion and he bore no message but this: that the members of the First District Branch should select one or two men and one or two alternates so as to insure representation, send them to Albany to meet like medical men, to go over this bill, and to take out or modify things that might be objectionable, and to get the bill in the form that they liked best and then to present it to the Legislature again. Efforts had been made to meet all reasonable and just objections to the bill. Some had said that the bill was a step toward health insurance, that monstrosity and insult. This bill had no relation to health insurance. He felt as many of his hearers and as the people in the Health Department felt toward the health insurance bills. The Health Center bill was drawn by doctors and presented by doctors to doctors for revision, and it hoped to care for the interests of the profession. It provided for assistance in the maintenance of hospitals and for construction, enlargement, and administration of laboratories, and it also provided that an effort be made to see that the medical profession received its just dues. He hoped that the medical profession would always be allowed to select the objects of their own charity, and that they should not have the municipality or the State cast charity upon them. He hoped they would see their way to send representatives to Albany.

Dr. HENRY LYLE WINTER pointed out that it would be impossible for them to send representatives to Albany, inasmuch as under the constitution of the State Society and under the bylaws of the society the district branch societies had no executive functions, being organized as scientific bodies only.

Dr. CHARLES I. REDFIELD of Middletown said he had studied both the health insurance and the health center bill for several years, and he wished every man would do the same. Dr. Duryee had stated that State education and State medicine were correlative. He did not see any relation between these two things. The doctor worked as an individual with individuals, and he did not see why they should come under State medicine. The objection to the bill was that mayors, members of town councils, and county supervisors would say who should treat people. The doctor did not want to be controlled politically. The solution, it seemed to him, was that if the doctors wanted to make a membership corporation group in any locality they could do it without the aid of the politicians. Not that he did not believe in group diagnosis, for he thought it a splendid thing, and that all should have all laboratory facilities; but he objected to having them subsidized by the State. No doubt both the health insurance and health center bill could be amended so as to be perfectly satisfactory to the politicians. The State Board of Health said that the health center bill was the complete answer to the compulsory health insurance bill. Therefore, it would seem that it must include the main ideas of compulsory health insurance. Dr. Redfield then showed that the cost of operating the health center plan would lay an excessive burden on the taxpayer. It was estimated that the cost of health insurance would be about $125,000,000 annually to the State and the health center idea could not be carried out for much less than this amount. Orange county had been selected as a place in which to try out the health center idea. Following the clinic a questionnaire was sent out to the doctors who had sent patients to that clinic to find out what they thought of it. Of 110 doctors practising in Orange county 79 sent patients to the clinic. Many of the replies to the questionnaire were quoted, showing that the clinic had not furnished as much help as it had been hoped it would give. One objectionable feature was the length of time it required to get the data regarding the patient. That often came so late as to be of no practical value. The impression to be derived from the evidence presented was that the general practitioner did not want a bureaucracy of thsi kind.

Dr. HENRY LYLE WINTER took exception to the statement that no bill affecting public health and the medical profession had ever been drawn up and presented to the Legislature by the medical profession. While doctors might nto actually have written the bills, they had been back of a great deal of legislation which concerned both the medical profession and public welfare. Dr. Winter related an experience he had had in connection with certain research work that was conducted under a State appropriation which demonstrated how utterly impossible it was to conduct work of that kind under a state department without constant interference, and declared himself against any system of practising medicine backed by any department of the State of New York.

Dr. JOHN P. DAVIN of New York asserted that the medical profession had advanced to the lofty place it now held by its own unaided efforts. It was the one profession that had grown through its own efforts. He did not believe in the introduction of any modern mechanical contrivance for making diagnosis and treating the patient. State medicine was being practised with a brass band and all the paraphernalia designed to excite public interest. On the other hand, the true practice of medicine was carried on quietly; the true physician did what he could, sometimes very little, sometimes a great deal, but he did it in a quiet and dignified manner. We must keep this splendid heritage in our own hands; the time had not come to surrender our prerogatives to political masters. Dr. Davin then contended that it was the rank and file of the profession that had come forward and defended the profession against compulsory health insurance. He called attention to other organizations which tended to commercialize and socialize medicine, and particularly to the Workmen's Compensation legislation which was still a thorn in the flesh of the profession. He thought this should be taken care of before we entered into any new fields.

Dr. J. RICHARD KEVIN of Brooklyn wished to speak on this subject, not as an officer of the Medical Society of the State of New York, but merely to express his individual opinion. It seemed to him that this whole problem resolved itself into a question of principle. Others had spoken of State medicine, and possibly it was coming; indeed, it was here like an incipient disease. Already New York City spent one million dollars a year on its health department. State medicine was gradually and insidiously growing. Dr. Kevin called attention to some of the pitfalls of statistics as collected by a State Department of Health. Some counties did not have a sufficient number of physicians so the deduction was drawn that the whole State needed this help, and the Health Center bill was devised to meet this lack. The police powers of the Health Department were immense. It was their function to do the big things that the individual members of the profession could not do; but it should keep to its function, namely, the prevention of disease; it should not treat disease. In the first place, the name itself, Health Center, was not honest; they were not health centers, but disease centers. Dr. Kevin said he was in favor of health centers with certain restrictions. The Health Department already had a great deal to do and was not doing it as well as it should. Instead of a health center bill it seemed to him it would be better for them to simply provide pathological and laboratory facilities in districts where these were needed. He believed, however, in sustaining the efforts of the State Health Department and not in abusing it.

Dr. EMERY of Brooklyn believed, with Dr. Kevin, that the State Department of Health was doing a great work. He did not know all the details of the Health Center bill, but he believed it overstepped the privileges of the Health Department. In certain districts there might be a shortage of physicians. Twenty years ago 3500 men were graduated from the medical colleges each year; now there were only about 2000, and a great many of these did not go into the practice of medicine, but into some departmental work. As long as the present premedical requirements remained they would not get men to supply the rural districts. A boy from a rural district could not afford to take two, four, or six years in a classical college and then four years in a medical college. If they wished to supply physicians to rural localities a medical course would have to be arranged which would permit boys from rural districts to study medicine.

Dr. DURYEE, in closing the discussion, explained that it was not the business of the health center to practise medicine, and expressed gratification that those present had taken such an interest in matters that affected the medical profession, even though he thought they did not take quite the proper view regarding the Health Center bill.

Encephalitis Lethargica (Epidemic Encephalitis).—Dr. HENRY LYLE WINTER of Cornwall read this paper, in which he related his experience with this disease. He stated that for the present we must regard polioencephalitis and encephalitis lethargica as distinct diseases. There was no question among neurologists but that encephalitis lethargica was a clinical entity. The fact that encephalitis occurred most frequently in those who had suffered from influenza, and that the disease made its appearance about six months after the influenza epidemic of 1917, clearly pointed to an etiological relationship. Beyond this the cause of encephalitis was unknown. All that could be said was that probably it was an air-borne infectious disease, and also probably contagious. The pathological changes might occur in any part of the brain, and might involve the pia. The writer's series of 20 cases furnished two autopsies, in one of which the pia was markedly involved, while in the other it had suffered no change. The lesions in the brain itself were similar in both cases, consisting of numerous pinpoint hemorrhages in both the gray and white matter of the brain, and especially of the gray matter of the basal ganglia. There was very little actual destruction or organic impairment of the nerve cells. It was in accord with clinical experience as well as with pathological findings that some form of disturbed consciousness was present in every case of encephalitis; this seemed to be the only symptom which was always present. In all of the writer's cases the patient could be aroused to active consciousness, could fix his attention and would give rational replies to even complex questions. After reviewing Tilney's classification of the various types of encephalitis the points in diagnosis which Dr. Winter had found most helpful were suddenness of onset and double vision. The latter occurred in five of his patients while they were at work, apparently in good health. It was necessary to regard any sudden neurological disturbance with suspicion. The range of temperature was low except in severe cases. The pulse showed no characteristic changes, except that in some cases it tended to become irregular and intermittent, probably because of disturbed innervation through cranial nerve irritation. The respirations were usually altered, being retarded or accelerated in accordance with the character of the disturbance of consciousness. They might be altered by cranial nerve involvement, the excursions of the chest walls being different on the two sides. The blood pressure was taken at intervals in five cases of the lethargic type and was persistently low. The blood count was made in 15 cases and showed a white count of from eight to ten thousand. The spinal fluid was under pressure in some cases, but increased pressure was not the rule. All the cases in this series showed an increaed cell count, from 80, the lowest, to 250, the highest. In other respects the spinal fluids were negative. Three of these cases showed evidences of cerebral pressure, the symptoms being so marked in two as to suggest the possibility of brain tumor. In these cases the eye grounds showed optic neuritis and hemorrhages into the retina. Except for these three cases the ophthalmoscopic findings were negative. The prognosis was always doubtful in every case. The possibility of more or less permanent invalidism in a variety of forms must not be lost sight of. There was no specific treatment of encephalitis. The maintenance of nutrition and elimination were essential. He had obtained the most satisfactory results with meat broths and cereal gruels made with water, and had used prepared peptonoids with advantage. Milk, and foods made with milk, had proved difficult to digest, and he did not use them. Feedings should be given every three hours. Water was necessary in fairly large quantities. Plain water was borne poorly, so he gave at least a quart of albumin water in twenty-four hours, in addition to the feedings. The low blood pressure referred to indicated asthenia, and this contraindicated the use of active catharsis. Constipation, if present, should be corrected by enemata. Restlessness demanded the use of sedatives. He had been successful with two to five grain doses of chloral combined with bromide. Heart irregularities might be met with the usual drugs. In this connection he had been much impressed by the effect upon the general condition of a few doses of digitalis given to correct an irregular heart. One of the physiologically tested preparations was given hypodermatically. After the second dose the patient's lethargy became less pronounced. The drug was continued and the mental condition cleared up in a few days and continued clear. It was possible, or even probable, in this instance, that the recovery was merely coincidental. At the same time, if one considered the pathology and the effect of digitalis on the vascular system it was not unreasonable to assume that the drug *could* be of value. He did not feel that the routine employment of repeated lumbar puncture, which had been advised by several neurologists, was desirable or even indicated. In those cases which exhibited pressure symptoms it should be done with sufficient frequency to relieve the symptoms. In the majority of cases, however, no pressure symptoms were present. The pathological changes were perivascular extravasations and hemorrhages, and theoretically reduction of the pressure in tissues surrounding and supporting the vessels increased the liability to extravasation of blood and the invasion of these tissues. His own clinical experience also was against this procedure. Dr. Winter said his purpose in presenting this subject in a rather sketchy way was to direct attention to the wide variation of symptoms which might occur in this disease.

Dr. MORRIS STARK spoke of the difficulty of making

a diagnosis between poliomyelitis and lethargic encephalitis. The spinal fluid should always be examined. He cited one case in which there was very little lethargy, but in which there were some choreic movements and finally paralysis of the internal recti of the eye. In this case the spinal fluid showed nothing. Dr. Bernhard Sachs examined the patient and stated that there was cerebellar involvement. Dr. Stark asked Dr. Winter whether he had employed spinal lavage in any of his cases after having removed the spinal fluid, a procedure that had been recommended.

Direct Hernia.—Dr. J. P. HOGUET of New York City made this presentation in which he expressed the opinion that hernia was not regarded as seriously as it ought to be, and that enough study had perhaps not been given it when one considered its frequency. In New York City probably 10 per cent. of the operations performed were for hernia of some kind. Further, of all types of hernia, direct hernia formed about 10 per cent. That figure was not exactly accurate but was arrived at from the percentages of men who did the largest part of the hernia operations performed in the city. The unfortunate thing in connection with hernia from the economic standpoint was that the largest percentage of hernia cases occurred during the fairly active working years. Hernia scarcely ever occurred in those under fifteen years of age. It was rarely seen in women, but in men between the ages of 30 and 60 years in the majority of cases. It was quite possible that a massive hernia might start as an indirect hernia, that in the last stage there might be a complete giving away of the entire inguinal ring, and that the indirect and direct hernia might exist as one. Many recurrences followed operation for indirect hernia not due to a recurrence of the indirect hernia but to the fact that a direct hernial sac was overlooked at the time of the operation, and shortly after the direct hernia made its appearance and grew progressively larger. In operating for indirect hernia one should make sure that a direct hernia did not exist. It was not necessary before operation to make an exact diagnosis as to the type of hernia, since one could plan his operation at the operating table. There were cases of direct hernia in which an ordinary Bassini operation with transplantation of the cord—and he believed the cord should be transplanted in every case—did not effect a permanent cure. There were cases in which the conjoined tendon was not taut and could be brought down and sutured to Poupart's ligament, with very satisfactory result. In certain cases, on the other hand, the conjoined tendon was thinned out, and when sutured to Poupart's ligament made a very thin wall against recurrence of the hernia. In such cases it was necessary to have some kind of reinforcement, and naturally the operation which suggested itself was transplantation of the rectus muscle. After retracting the conjoined tendon forward and inward, the external portion of the rectus was split, pulled down and the fibers stitched to Poupart's ligament. That was an excellent operation where the rectus muscle was broad enough, but there were cases in which it was close to the midline. In such instances it had occurred to him that it might be possible to reinforce the conjoined tendon by suturing down the reflected portion of the aponeurosis of the external oblique. For a long time it had been his routine procedure to put the most internal stitch through the reflected portion of the external oblique, then through the conjoined tendon and then through Poupart's ligament. He had also devised a scheme for converting an indirect into a direct hernia, which avoided injury to the bladder wall. These procedures Dr. Hoguet illustrated by lantern slides. In closing he said it was surprising how badly the average hernia was operated upon. It was estimated that there were recurrences in over 15 per cent. of the cases. That should be remedied. A large number of cases having recurrences had been operated upon by the Bassini method. With the intelligent use of transplantation of the rectus or the suturing down of the reflected aponeurosis, the recurrences were a little over 7 per cent. By using both rectus transplantation and suture of the reduplicated aponeurosis, recurrences were reduced to 2½ per cent., which was better than the results obtained by the simple Bassini operation.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DIATHERMY IN MEDICAL AND SURGICAL PRACTICE. By CLAUDE SABERTON, M.D. 138 pages with 33 illustrations. Published by Paul B. Hoeber, New York.

PRACTICAL BACTERIOLOGY, BLOOD WORK, AND ANIMAL PARASITOLOGY. By E. R. STITT, M.D. 633 pages with illustrations. Published by P. Blakiston's Son & Co., Philadelphia.

THE STORY OF THE AMERICAN RED CROSS IN ITALY. By CHARLES M. BAKEWELL. 253 pages with illustrations. Published by the Macmillan Co., New York.

OCCUPATIONAL AFFECTIONS OF THE SKIN. By R. PROSSER WHITE, M.D. 360 pages with illustrations. Published by Paul B. Hoeber, New York.

THE SYSTEMATIC TREATMENT OF GONORRHEA IN THE MALE. By NORMAN LUMB, M.D. 123 pages. Published by Lea & Febiger, New York.

THE ESSENTIALS OF HISTOLOGY. By Sir EDWARD SHARPEY SCHAFER, M.D. 577 pages with illustrations. Published by Lea & Febiger, New York.

SYPHILIS. By LOYD THOMPSON, M.D. 486 pages. Illustrated with 81 engravings and 7 plates. Published by Lea & Febiger, New York.

PRINCIPLES OF BIOCHEMISTRY. By T. BRAILSFORD ROBERTSON, M.D. 633 pages. Illustrated with 49 engravings. Published by Lea & Febiger, New York.

PUBLIC HEALTH AND HYGIENE. Edited by WILLIAM HALLOCK PARK, M.D. 884 pages. Illustrated with 123 engravings. Published by Lea & Febiger, New York.

SURGERY, ITS PRINCIPLES AND PRACTICE. By ASTLEY PASTON COOPER ASHHURST, M.D. 1202 pages with 14 colored plates and 1,129 illustrations in the text, mostly original. Published by Lea & Febiger, New York.

KOMPENDIUM DER AUGENHEILKUNDE. By Prof. Dr. PAUL SILEX. 304 pages with illustrations. Published by S. Karger, Berlin.

GEBURTSHILFLICHES VADEMEKUM. By Prof. Dr. A. DUHRSSEN. 330 pages with illustrations. Published by S. Karger, Berlin.

THERAPEUTISCHES VADEMEKUM FUR DIE KINDERPRAXIS. By Dr. HANS KLEINSCHMIDT. 196 pages. Published by S. Karger, Berlin.

GYNÄKOLOGISCHES VADEMEKUM. By Prof. Dr. A. DUHRSSEN. 290 pages with illustrations. Published by S. Karger, Berlin.

INNERE SEKRETION UND DEMENTIA PRAECOX. By Dr. OSCAR LESSING. 63 pages. Published by S. Karger, Berlin.

KOMPENDIUM DER KINDERHEILKUNDE. By Prof. Dr. ALBERT NIEMANN. 334 pages. Published by S. Karger, Berlin.

LEITFADEN DER ELEKTRODIAGNOSTIK UND ELEKTROTHERAPIE. By Prof. Dr. TOBY COHN. 226 pages with illustrations. Published by S. Karger, Berlin.

DIE ABDERHALDENSCHE REAKTION. By Dr. GOTTFRIED EWALD. 210 pages. Published by S. Karger, Berlin.

DIE SCHLAFSTÖRUNGEN UND IHRE BEHANDLUNG. By L. E. BREGMAN, M.D. 136 pages. Published by S. Karger, Berlin.

DIE BEHANDLUNG SCHWÄCHLICHER KINDER IN OFFENTLICHER FÜRSORGE. By Dr. JULIUS RITTER. 40 pages. Published by S. Karger, Berlin.

UBER DISPOSITION. By Dr. FELIX V. SZONTAGH. 347 pages. Published by S. Karger, Berlin.

STUDIEN UBER DARMTRÄGHEIT. By Dr. FRANZ XAVER MAYR. 266 pages. Published by S. Karger, Berlin.

BLOCK ANESTHESIA. By ARTHUR E. SMITH, M.D. 895 pages with 595 illustrations. Published by C. V. Mosby Company, St. Louis.

PSYCHOPATHOLOGY. By EDWARD J. KEMPF, M.D. 762 pages with 87 illustrations. Published by C. V. Mosby Company, St. Louis.

MEDICAL RECORD VISITING LIST, or Physicians' Diary, for 1921. Revised. Published by William Wood and Company, New York.

Miscellany.

The Nights of a Bordeaux Practitioner—Dr. de Coquet contributes a feuilleton with the above title to the *Journal de Médecine de Bordeaux* for Sept. 25, 1920 xci., 18. In this he outlines the activities of a supposititious Dr. Boniface who in the course of his active life has gathered more grey hairs than yellow backs. His means are very moderate and in lieu of an automobile he makes his rounds on a bicycle. In the evening after having patriotically read the two Bordeaux medical journals, the *Journal* and *Gazette*, he fixes his itinerary for the morrow and turns in, as he hopes, for the night. The neighborhood being a quiet one and he himself fatigued he at once falls asleep. But hardly has a half hour elapsed before the doorbell rings loudly. Probably a confinement due shortly, he thinks. But the speaking tube evokes no reply save a volley of laughs from a party of young people returning from a moving picture show, who wish to show off before one another. It reminds him of July 14, the Bastile holiday, when that sort of thing might be tolerable.

The doctor tries to go back to sleep but he is aroused and his mind begins to run on a sick patient. Besides he is disturbed by the parade of pleasure seekers home going from the theaters and restaurants. Not until after midnight does he once more sleep. Still later parties return from gatherings of social character and in vehicles. The coachmen make much noise, not for the sake of being noisy, but to fix attention of the fares on the naturalness of a good tip. The hilarious fares are shouting choruses and the doctor sooner or later wakes once more. He hears two drunks conversing under his window.

Sleep has now become impossible. He hears the mournful sirens of steamboats in the harbor and the whistles of incoming trains, and later the early market wagons, and the street sweepers with their wooden shoes. The foreman of these issues his commands in a loud voice. One Sabatier, a sweeper, is "off the job" and the foreman starts a sort of hue and cry for him. The fugitive is finally located and reports verbally to his chief from a remote locality. The foreman, now relieved, breaks out into a patriotic song. After the sweepers have finished, the "night soil" wagons pass by, the drivers inveighing loudly against their horses for some breach of conduct. The heavy vehicles shake the house as they rumble by. At 5 o'clock the first trolley cars for the laborers begin to run. The merchants are taking down their shutters. Workers hurry by on foot and one playfully rings the bell. The doctor is dozing a little but soon his servant rouses him, for his regular hour for rising has come. The first thing to be done after dressing is to make written complaints to the responsible city officials, but the sufferer chances to think of the well-known Dr. Boileau, a Parisian physician, who several years ago had indited a complaint of the same sort in verse for the sake of the greater appeal, but without result. He asks himself what would be the use and consoles himself with the likelihood that on the following eve he will be so sleep famished that nothing will keep him awake.

What Was the Sacred Plant of the Ancient Mexicans?—This subject is discussed at great length in the *Revista Ibero-Americana* for July, 1920, xliv, 7. Dr. Suarez, the author, states that the identity of the *Ololiuhqui* is still an enigma. It has been identified with the *Ipomes sidæfolia*, a plant that grows in Oaxaca, and with the *Convolvulus microcalyx*, apparently on insufficient evidence. The author uses the shortened term *ololique* to distinguish the historical plant. The first Spaniard to mention it was Hernandez, a well-known physician, in a work on the plants of New Spain, published in Latin between 1570 and 1577. This underwent a translation into Spanish and as recently as 1888 was reproduced in *fac simile*. In this reprint we find that the *ololique* (to use the more modern contracted form) was the same as the *cohuaxihuitl*. The word *ololiuhqui* is said to mean "plant with roundish leaves," from *olola*, a round object; while *cohuaxihuitl* is said to signify "green snake," or figuratively the "snake herb," of which the leaves were heart-shaped. This plant, whatever it was, seems to have been a cure-all and to have been used to expel the cold, to cure broken bones and the relaxed hips of women (from childbirth?) as an antisyphilitic, etc. Among other activities it was good against mania and hence was once associated with the poisonous *Solanaceæ*. But from the descriptions, botanical and pharmacological, little idea of its identity can be obtained. The plant was a natural product of the State of Oaxaca only, and there is no evidence that it was cultivated elsewhere.

Arsonval on the History of High Frequency Currents in Therapeutics.—The well known inventor of the Arsonval current which was termed arsonvalization by Benedikt of Vienna gives in *La Médecine*, June, 1920, a brief outline of the history of our knowledge since the year 1903. He sums up his circuit as an alternating one with millions of cycles a second in place of 80 to 100. The number should be from four to six millions. The author began to study simple alternation in 1881 and the greatest number of alternations then available was 10,000. This frequency was found to be innocuous. Improvements in technique gradually led to increase of frequency and in 1893 he was able to pass through his body a current of 900 volts times 0.8 amperes, equivalent to 720 watts, without any sensations. Naturally the same amount of electric energy in a galvanic circuit would have been fatal. He showed at the same time that often in apparent death from industrial alternating currents of low frequency reanimation is possible by means of artificial respiration. Although diathermy is claimed by Germans and Austrians as comparatively new, the author shows that he discovered the principal phenomena in the last century. In 1893 he passed 3,000 milliamperes through his arm with the genesis of heat and in 1896 he first used diathermy in the clinic and showed that it could slow metabolism. The experiments attracted no attention because at that time there was no electric installation in the hospitals. The term arsonvalization could with equal propriety be applied to the diathermic circuit.

INDEX.

A

Abdomen, acute, acidosis in, 492.
Abnormalities of the gastrointestinal tract in persistent constipation in children and the application of roentgenograms in their recognition, 830.
Abortion, bacillus aerogenes septicemia with methemoglobinemia following, 452; complicated by sepsis, the treatment of, 752; missed, 455, 752.
Abrahamson, Isador: the epidemic of lethargic encephalitis, 969.
Abrams, Albert: clinical localization of the vermiform appendix, 229.
Abscess, acute, of the lateral wall of the laryngopharynx, 587; dysenteric hepatic, medical treatment of, 702; extradural and subdural, following suppurating frontal sinusitis and osteomyelitis of the frontal bone, 587; fixation, in the treatment of bubonic plague, 317; of the larynx in children, 64; fixation, in the treatment of lethargic encephalitis, 523; subacute perinephric, of non-renal origin, 785.
Achylia, gastric, the treatment of, 939.
Acid base equilibrium in disease, studies of the, from the point of view of blood gases, 285.
Acidosis, in acute abdomen, 492; of the recurrent vomiting type, 407; the carbohydrates and, 740; syndrome, the, 820; tissue, vs. blood acidosis, 467.
Accident, and pneumonia, causal relation between, not known, 691; policy, statements in proofs of loss—on use in hypothetical questions, 691; street, in London, 614.
Actinic rays, 922.
Actinomycosis treated with methylene blue and roentgen ray, 996.
Adams-Stokes syndrome, the, 923.
Adenoid vegetations in the adult, 703.
Adenomata of the carotid gland, 282.
Adenomyomata, submucous, 748.
Adolescence, sex conflict in, 204.
Adrenal, action, notes on, 845; support, the principles of, 391.
Adrenalin, pilocarpine, and bronchial asthma: response to, 668; the effect upon the blood pressure of the injection of, in dementia precox, 364.
Adrenine, treatment of persistent vertigo with, 654.
Adults, adenoid vegetations in, 703; young, children and, the effort syndrome in, 372.
Advertising, 1065.
Africa, French West, the medical school of, 42.
Aged, acquired syphilis in the, 730; the prognosis of erysipelas in the, 819.
Ainhum in Peru, the first case of, 84.
Air, expired, relations between the temperature of the, and the cutaneous temperature, 661; tract, upper, results of treatment of malignant disease of the, by radiation, 581.
Albumin, egg, in stools, precipitins for, 373; soluble, blood and, on the significance of, in the stools, 448.
Albuminuria, functional, in college students, 1071.
Alcohol and its influence on body and mind, 530; and opium, the mental effects of, 577; and the body, 570; injections, the role of deep, in the treatment of trigeminal neuralgia, 365; its status quo ante, never! 186; poisoning, acute methyl, 533; versus phenol—the value of the "no good," 956.
Alcoholic beverages, the toxic coefficient of, 360.
Alcoholism, simulation and, 872.
Alexia, pure, pure aphasias à propos of a case of, 1059.
Alkalinity, decreasing body, the therapeutics of, 471.
Alkaptonuria, 872.
Allergy, anaphylaxis, and immunity in hay fever and asthma, 216.
Allergies in chronic diseases, 733.
Alpine lamp, see *Lamp, quartz.*
Alopecia, an epidemic of, 317; areata, the treatment of, with quartz lamps (Kromayer and Alpine), 895.
Alimentary glycosuria, the diagnosis of hepatic insufficiency by means of, 945.
Alsever, W. D.: practical methods of heart study and their relative values, 345.
Alvarenga prize, 780.
Ambidexterity, is, advisable, 150.
Amenorrhea, accidental, 694; and marriage, 983.
Anaërobes, some observations on the role of certain, in the intestinal flora of infants, 373.
Analgesia, oral, 630.
Anaphylaxis, alimentary, actual state of our knowledge of, 573; allergy, and immunity in hay fever and asthma, 216; parenteral protein treatment of arthritis, with special reference to milk injections; its relation to, 47; report of a case of, following an intradermal protein sensitization test, 371.
Anaphrodisia from mercury, 65.
Anastomosis, end-to-end, of the intestine by presection sutures, 618; healing of end-to-end intestinal, with especial reference to the regeneration of blood vessels, 618; resection, of transverse colon for carcinoma, jejunal colic fistula sequel to, 753.
Anatomical diagnosis, a discussion of rare cases of, 115; names, a plea for simple, 617.
Anatomy, applied, of the pelvic bowel, 900; physiology, and pathology of the tonsillar structures in relation to cryptogenic infections, 593.
Anders, James M.: the treatment of cardiac arrhythmias, 512.
Anderson, H. B., Mann, R. W., and Sharpe, N. C.: chronic tonsillar infections, 590.
Anemia, hemolytic, one factor in the mechanism of hemolysis in, 829; pernicious, in uremic nephritis, 574; pernicious, surgical aspects of, 1001; pernicious, with especial reference to treatment, 998; simple, blood regeneration after, as influenced by various dietary factors, 289; splenic, report on three cases of, treated by splenectomy, 1041.
Anemias, the primary; pathological consideration, 1003; the relationship of the, to life insurance, 533.
Anesthesia, ether-oil-colonic, the toxic thyroid; its treatment by, 749; resuscitation in death under, 997; the psychic factor in—death in status thymicus, 65.
Aneurysm, Rasmussen's, 822.
Angina, Ludwig's, is, a gas phlegmon? 946; streptococcic, with purpura hemorrhagica and multiple infarcts of the skin and subcutaneous tissue in a child two years old, healing under Dakin's solution, 371; Vincent's, 619; Vincent's, and sarcoma of the pharynx, one condition following the other in the order named, report of a case of syphilis, 581.
Anomalies of the spine, 22.
Anorexia, nervous, 778.
Anosmic-epileptic family, 737.
Anoxemia, 576.
Anthropology, international institute of, 783; of modern civilized man, 282; the usefulness of, 576.
Antigens, a study of the preparation of, from cultures of the tubercle bacillus for the complement-fixation test, 288.
Anthrax cured with horse serum, 612; cutaneous, 1071; in French West Africa, 755; in shaving brushes, 25; mistaken for erysipelas, 924.
Antiepidemic measures, antiquity of, 587.
Anxiety neurosis, 925.
Aorta and lung, a study of the progressive changes in the, as shown by *x*-ray in tuberculosis and syphilis, 499; ruptured, due to accident, 314.
Aortitis, specific, 237.
Aphasias, pure, à propos of a case of pure alexia, 1059.
Apneic pause, the voluntary, 526.
Appendectomy, sequelæ of, 611.
Appendicitis, intestinal parasites as a cause of: report of a case, 143; season of year and weather, 449.
Appendicostomy and cecostomy, a brief experience with, for intestinal stasis in epilepsy and neurasthenia, 449.
Appendix pathology, non-rotation of the colon and its relation to, 83; vermiform, clinical localization of the, 229.
Applications, hot and cold, effects of, on the superficial and deep temperatures, 744.
Arachnoid, the cells of the, 829.
Argonne Association, the, 370.
Army, syphilitic cardiovascular disease in the, 34.
Arsenic in Parkinson's disease, 822.
Arsenobenzol, treatment of trachoma by, 1036.
Arsonval on the history of high frequency currents in therapeutics, 1081.
Arsphenamin and its derivatives, review of the untoward effects fol-

lowing, 911; the use of in non-syphilitic diseases, 489; the intensive administration of, 659.
Arrhythmia, cardiac, the treatment of, 512.
Arterial fibrosis, hypertension and, 280; hypertension, treatment of, 743.
Arteries, cerebral, employment of diathermy and galvanism in the management of sequelæ of occlusion, partial or complete, and of rupture of the cerebral arteries, 851.
Arteriosclerosis, etiology and symptomatology of, 315; the three-fold menace of the present day, 757.
Arthritis and electrotherapy, 838; chronic, some observations on, 248, 534; deformans, 168; parenteral protein treatment of, with special reference to milk injections; its relation to anaphylaxis, 47; purulent, gentian violet in the treatment of, 447.
Arthroplasty, with demonstration of patients and exhibition of x-ray plates, 411.
Ascites, disappearance of, as a consequence of intraperitoneal injections of Ouabaine, 535.
Asphyxiation, partial, in an infant, resulting from the inhalation of dusting powder, 1027.
Asthenia of epidemic encephalitis and of grippe, 491.
Asthenics and maniacs, oscillometry in, 492.
Asthma and hay fever, observations on, 1045; bronchial, radiation of the hypophysis for, 661; bronchial, ipecac sensitization and, 784; bronchial: response to pilocarpine and adrenalin, 668; hay fever and, spirits of camphor in, 588; hay fever and, diagnostic tests in, 238; hay fever and, allergy, anaphylaxis, and immunity in, 216; tincture of cockroach for, 168.
Astigmatism, disturbances of the heart and liver caused by low grades of, 617.
Asylums, war, 613.
Ataxia, acute cerebrocerebellar: with reports of cases, 327.
Athletics and increasing heart disease, 439.
Atlas, diagnosis of sex through measurements of the, 401; the sexual differences of the, 630.
Atresia, congenital, of the esophagus, 370.
Atrophy of the liver, causation and pathology of, 871.
Audition, colored, 618.
Aulde, John: the diet and health, 9.
Aural aftermaths of influenza, 810.
Auscultation of the lungs by electrical means, refinement in methods of, 247.
Autointoxication, neuritis due to, 1050.
Autoserotherapy of gonorrheal epididymitis, 275.
Autosuperinfection, alleged syphilitic, 107.
Aviators, experienced, the labyrinthine reactions of, 197.
Award without requiring examination by physician held erroneous, 985.

B

Baar, Gustav: new procedure for the prevention of spinal puncture headache, 598.
Babcock, W. Wayne: the control of hyperchlorhydria and its consequences by cholecystogastrostomy, 476.
Babies, bottle-fed, small doses of ipecac in the digestive disorders of, 535.
Baby, the rich, and its keeper, 1029.
Bacilli, acid-fast chemotherapy and 906.
Bacillus abortus bovinus preliminary observations on the pathogenicity for monkeys of the 331; aerogenes septicemia with methemoglobinemia following abortion, 452.
Backache from the viewpoint of the general surgeon 572; prostatic, 144.
Bacteria, pathogenic, retention crypts in the infratonsillar nodules as common and extensive harbors of, 580; some experiments to determine the persistence of extraneous, in the gastro-intestinal tract of guinea pigs as influenced by diet, 374.
Bacterial intoxication, 447.
Baldwin, Hugh A.: skin grafting, 686.
Balneological stations in Belgium, 237.
Bands, obstruction of the superior mesenteric vessels from, with threatened gangrene of the greater part of the small intestine; recovery, 749.
Barber, W. Howard: recovery of a needle from tendon of flexor longus hallucis, 728.
Bardes, Albert; aural aftermaths of the influenza, 810.
Barnhill, John F.: anomalous sigmoid sinus thrombosis, with report of a case, 388.
Basal metabolism, a study of the correlation of the, and the pulse rate in patients with exophthalmic goiter, 165; studies in, 407.
Bateson, J. C.: responsibility of the state for drug addicts, 1034.
Baths, Saratoga-Nauheim, a study of the natural, at Saratoga Springs, N. Y., 262.
Beates, Henry, Jr.: Horatio C. Wood, an appreciation, 393.
Bell, Robert: the nature of cancer, 444; the treatment of cancer, 354, 826.
Benjamin Rush for the Hall of Fame, 110.
Benzoate, benzyl, nonleucotoxic properties of, 280.
Benzosulphinide, the therapeutics of, 595.
Benzyl benzoate, nonleucotoxic properties of, 280; on the use of, in persistent hiccough, 146.
Bequests to hospitals, 650.
Beriberi (?) in Spain, a case of, 608.
Bezredka's discovery, 1064.
Bichloride poisoning, kidney function in a case of, 56.
Biddy and the coal bin, a case of polyglandular disease, 351.
Bile elimination, the hepatic margin of safety in, 284.
Bilharziosis in the Near East and Mediterranean south shore, 821.
Biliary tract, liver and, some interesting surgical conditions of the, 747.
Biloculation of the stomach, the gastric pouches in, 526.
Biochemistry in the French University of Strassburg, 619.
Biological movement, the, during the war, 956.
Birth rates and world wars, 999.
Bishop, Louis Faugères: a report of one thousand heart patients subjected to a complete cardiac examination with an account of the therapeutic results, 508.
Bismuth mixtures, lung mapping by the injection of, in the living, 585.
Blackwater fever, notes on, 997.
Bladder, rupture of, during labor, 747; tumors of the (pathology), 998.
Blau, Arthur I.: errors in the diagnosis of the contagious diseases, 352.
Bleeding, non-malignant uterine, some immediate effects following the use of radium, 453.
Blind to "see" by ear, 714.
Blindness, causes of, 741; hysterical, from shock of surgical operation compensable under Workman's Compensation Act, 902; in Saharan oasis towns, 151.
Bliss, A. Richard, Jr.: proposed vegetable deletions, 265.
Bloch, syndrome of, 401.
Block, reverse, nodal rhythm, with, and paroxysmal tachycardia, 286.
Blood alkali reserve, with experimental infections, 828; an accurate and simple method of testing the coagulation time of, 436; analyses in some ophthalmic conditions, 250; and soluble "albumin" in the stools, on the significance of, 448; and urine in pancreatic disease, 533; cells, red, the fate of subcutaneously injected, 419; chemistry, some phases of, of practical use to the practitioner, 169; diurnal variations in the hemoglobin content of the, 701; findings five years after splenectomy, 371; gases, studies of the acid base equilibrium in disease from the point of view of, 285; nitrogen, effect on blood pressure and of the ingestion of large amounts of fluid, 249, 286; nitrogen, in infants and children, recent studies in, 419; pressure, abnormal, the clinical significance and therapeutic indications of, 856; pressure and blood nitrogen, effect on, of the ingestion of large amounts of fluid, 249, 286; pressure in Graves' disease, a contribution on, 870; pressure, the effect upon the, of the injection of adrenalin in dementia precox, 364; ptosis; the gravity and significance of the resisting ability of the circulation; its measurement and significance, 956; regeneration after simple anemia as influenced by various dietary factors, 289; sugar estimation, sources of error in, 776; sugar in the, 870; sugar, studies on: the effect of blood on picrate solutions; a consideration of the limitations of the Lewis-Benedict method, 326; sugar tolerance test as an aid in the diagnosis of gastro-intestinal cancer, 285; the, in influenza, 102; transfusion, 534; transfusion, early history of, 755; vessels, healing of end-to-end intestinal anastomosis with especial reference to the regeneration of, 618.
Blumgarten, A. S.: the clinical significance and therapeutic indications of abnormal blood pressure, 856.
Bodily mechanics and medicine, 70; mechanics; its relation to cyclic vomiting and other obscure intestinal conditions, 328.
Body, human, the perfume of the, 672.
Boehme, Gustav F., Jr.: a method for standardizing the knee-jerk test and its measurement, 982.
Boil, Oriental, cure of, by emetine, 865; Oriental, first case of contagion of, in France, 158.
Boils and carbuncles, abortive treatment of, 367.
Bone-grafting of the fractured mandible, 239.
Bone sarcoma, conservative treatment of, 610; surgery outfit, complete, 121; transplantation, late result of a, 619.
Bones, metacarpal, the prognosis of fractures of, 401.

Book Reviews:

Advanced lessons in practical physiology for students of medicine, by Russell Burton-Opitz, 662.
Anæsthetics, handbook of, by J. Stuart Ross, with an introduction by Hy. Alexis Thomson, and chapters by William Quarry Wood and H. Torrance Thomson, 1039.
Antomie des menschlichen Gehirns und Rückenmarks auf Myelogenetische Grundlager, von Paul Flechsig, 620.
Anatomy, Cunningham's Manual of Practical, volume first, revised and edited by Arthur Robinson, 199.
Anatomy, Cunningham's Manual of Practical, volume second, revised and edited by Arthur Robinson, 283.
Anatomy, Cunningham's Manual of Practical, volume third, revised and edited by Arthur Robinson, 786.
Anatomy, topographical, of the limbs of the horse, by O. Charnock Bradley, 1039.
Anesthésie locale at régionale en otorhino-laryngologie, par les docteurs Georges Canuyt et J. Rozier, Preface du Professeur E. J. Moure, 536.
Anleitung zur Funktionsprüfung des Ohres (Prüfung des Gehör- und Gleichgewichts-apparates), von Dr. A. Sonntag und Dr. H. J. Wolff, 199.
Arteriosclerosis and hypertension, with chapters on blood pressure, by Louis M. Warfield, 704.
Atlas of the primary and cutaneous lesions of acquired syphilis in the male, by Charles F. White and W. Herbert Brown, 1039.
Backwaters of Lethe, some anesthetic notions, by G. A. H. Barton, 1039.
Birth control, pioneers of, in England and America, by Victor Robinson, 199.
Blood and urine chemistry, by R. B. H. Gradworth and A. J. Blaivas, 620.
Care and feeding of infants and children. A text-book for trained nurses, by Walter Reeve Ramsey, including suggestions on nursing by Margaret B. Lettice, 536.
Catarrhal and suppurative diseases of the accessory sinuses of the nose, by Ross Hall Skillern, 704.
Chemistry, treatise on general and industrial inorganic, by Ettore Molinari, 704.
Chorioepithelioma malignum, by Anton Sunde, 199.
Collected reprints from the George Williams Hooper Foundation for Medical Research, Vol. IV, 1918-1919, 242.
Dawn of Modern Science, by Albert H. Buck, 620.
Dermatology, a textbook of, by J. Darier, 242.
Development of the human body, a manual of human enbryology, by J. Playfair McMurrich, 786.
Diabetic manual for the mutual use of doctor and patient, by Elliott P. Joslin, 283.

Diagnosis and treatment of brain injuries, with and without a fracture of the skull, by William Sharpe, 787.
Diagnostic methods, chemical, bacteriological, and microscopical, by Ralph W. Webster, 662.
Diagnostisches Leitfaden für Sekret und Blutuntersuchungen (Theoretisches und Praktisches), von Dr. C. S. Engel, 786.
Diätetik der Magen und Darmkrankheiten. Von Prof. Dr. T. Boas. Nebst einen Abhang; Diätetik vor und nach Operationen aus Magen-Darmkanal, von Prof. Dr. G. Kelling, 536.
Die Indikationen zur Künstlichen Unterbrechung der Schwangerschaft, von Prof. G. Winter, 786.
Die Wurmfortsatzentzündung, von Dr. A. Rheindorf, 786.
Diseases of Children, Manual of, by James Burnet, 74.
Diseases of infants and children, by J. P. Crozer Griffith, 242.
Diseases of Nutrition and Infant Feeding, by John Lovett Morse, 199.
Diseases of the chest and the principles of physical diagnosis, by George Williams Norris, 31.
Diseases of the nervous system, a textbook of neurology and psychiatry, by Smith Ely Jelliffe, and William A. White, 493.
Eating to live long, by William Henry Porter, with introduction by Edwin F. Bowers, 575.
Education in war and peace, by Stewart Paton, 787.
Emolisi urinaria, by Prof. Alfredo Amati, 575.
Engebnisse der Gesamten Medizin. unter Mitarbeit hervorragender Fachgelehrten von Prof. Dr. Th. Brugsch, 493.
Epidemia de grippe de 1918-19, por Jose W. Tobias, 704.
Etude critique de l'étiologie des bronchites chroniques avec sclérose pulmonaire. Par Docteur Jacques Dalsace.
Exophthalmic goiter and its nonsurgical treatment, by Israel Bram, 831.
Faculty of the College of Physicians and Surgeons, Columbia University, in the city of New York, twenty-four portraits by Doris U. Jaeger, with a foreword by Samuel W. Laubert, 787.
Forests, woods and trees in relation to hygiene, by Augustine Henry, 662.
Geschlechtskälte der Frau (Eine Psychopathologie des Weiblichen Liebeslebens), von Dr. Wilhelm Stekel, 704.
Geschlechtskrankheiten ihr Wesen, ihre Erkennung und Behandlung, von Prof. Dr. Karlzieler, 159.
Grundriss der Augenheilkunde für Studierende und praktische Aerzte. Von Prof. Dr. A. Brückner und Prof. Dr. W. Meisner, 575.
Grundriss der Physiologie für Studierende und Aerzte, von Prof. Carl Oppenheimer und Prof. Dr. Otto Weiss, 199.
Gynecology, Atlas of operative, by Barton Cooke Hirst, 493.
Handbook der Speziellen Chirurgie des Ohres und der Oberen Luftwege, von Dr. F. Blumenfeld, 915.
Heart troubles: their prevention and relief, by Louis Faugères Bishop, 915.
Herman's difficult labour, revised and enlarged by Carlton Oldfield, 283.
Human parasitology, with notes on bacteriology, mycology, laboratory diagnosis, hematology and serology, by Damaso Rivas, 536.
Hungerödem, das, eine klinische und ernährungs-physiologische Studie, von Dr. C. Maase und Priv. Doz. Dr. H. Zondek, 410.
Hygiene, Dental and general, by Clair Elsmere Turner, with chapters by William Rice, 831.
Index of symptoms, with diagnostic methods, by Ralph Wimmington Liftwich, revised by H. N. Warner Collins, 536.
Inguinal hernia, the imperfectly descended testicle and varicocele, by Philip Turner, 575.
Infant feeding, principles and practices of, by Julius H. Hess, 74.
Klinische Linsestudier, by Harold G. A. Gjessing, 536.
Laboratory manual of pharmacology, by A. D. Bush, 368.
Lehrbuch der Volksernährung, by Prof. Dr. C. von Pirquet and Dr. E. Mayerhofer in conjunction with J. Heussler, E. Mayerhofer, Frau R. Miari, E. Nobel, Fr. Oberleitner, R. Schweeivecs, and R. Wagner, 915.
Manual of Tropical Medicine, by Aldo Castellani and Albert J. Chalmers, 493.
Massage and exercises combined, by Albrecht Jensen, 662.
Massage, the theory and practice of, by Beatrice M. Goodall-Copestake, 1039.
Mass physical training. For use in the army and in the reserve officers' training corps, by Joseph E. Roycroft. Foreword by Major-General W. G. Hahn, 368.
Mechanism and graphic registration of the heart beat, by Thomas Lewis, 915.
Medical Clinics of North America, May, 1920, Vol. 3, No. 6, 410.
Medical Record Visiting List or Physician's Diary for 1921, 1039.
Mehlfrüchtekur, die, in Diabetes Mellitus, von Prof. Dr. W. Falta, 451.
Menders of the maimed, by Arthur Keith, 74.
Movimento, il, demografico a Napoli durante la guerro (1915-1918). Prof. Giuseppe Cristalli, 575.
Normal Histology, with special reference to the structure of the human body, by George A. Piersol, 368.
One thousand one hundred pictured nouns in Italian, French and Spanish, with English index, by Clarence E. Swezey, 410.
Operative Gynecology, by Harry Sturgeon Crossen, 831.
Ophthalmic operations, a text-book of, by Harold Grimsdale and Elmore Bremerton, 620.
Organotherapy, Practical; the internal secretions in general practice, by Henry R. Harrower, 410.
Pathogenic microorganisms, by William Hallock Park and Anna Wessels Williams, 368.
Pathology, general and dental, with special reference to etiology and pathologic anatomy, by Julio Enledman, 242.
Pensions and the principles of their evaluation, by Llewellyn J. Llewellyn, 283.
Personal beauty and racial betterment, by Knight Dunlap, 199.
Pharmacopœia, the extra, revised by W. Harrison Martindale and W. Wynn Westcott, 410.
Physical diagnosis, a manual of, by Austin Flint, revised by Henry C. Thacher, 662.
Physical reconstruction and orthopedics, by Harry Eaton Stewart, 1039.
Physiological principles in treatment, by W. Langdon Brown, 283.
Physiology, a text-book of, for students and practitioners of medicine, by Russell Burton-Opitz, 159.
Physiology, principles of human, by Ernest H. Starling, 368.
Physiology, the new, in surgical and general practice, by A. Rendle Short, 1039.
Plastic surgery: its principles and practice, by John Staige Davis, 831.
Plastic surgery of the face based on selected cases of war injuries of the face, including burns, by H. D. Gillies, with chapters by W. Kelsey and R. Wade, 787.
Practical dietetics, with reference to diet in health and disease, by Alida Frances Pattee, 368.
Problem of the nervous child, by Elida Evans, 283.
Psychiatry, manual of, edited by Aaron J. Rosanoff, 31.
Psychoanalysis, by Barbara Low, 410.
Radiography in the examination of the liver, gall bladder, and bile ducts, by Robert Knox, 786.
Rambling recollections. An autobiography, by A. D. Rockwell, 620.
Rectum, handbook of diseases of the, by Louis J. Hirschman, 31.
Reiztheorie, die, und die modernen Behandlungsmethoden des Diabetes, von Priv.-Doz. Dr. R. Kolisch, 451.
Schwebelaryngoskopie und ihre praktische Verwerthung, von Gustav Killian, 159.
Sexual impotence, by Victor G. Vecki, 74.
Simplified infant feeding, by Roger H. Dennett, 662.
Surgical clinics of Chicago, December, 1919, Vol. III, No. 6, 493.
Swanzy's handbook of the diseases of the eye and their treatment, edited by Louis Werner, 410.
Symptoms in the diagnosis of disease, by Hobart Amory Hare, 283.
Syphilis, a treatise on etiology, pathology, diagnosis, prognosis, prophylaxis, and treatment, by Henry H. Hazen, 31.
Syphilis, the treatment of, by H. Sheridan Baketel, 74.
Toxémie traumatique (shock traumatique) dans les blessures de guerre, par E. Quénu, 159.
Trebalis de la Societat de Biologia, 159.
Tuberculosis, a study in the epidemiology of, with especial reference to tuberculosis of the tropics and of the negro race, by George E. Bushnell, 451.
Untersuchungen über die Myelomkrankheit, von Arvid Wallgren, 1039.
Use of colloids in health and disease, by Alfred B. Searle, with foreword by Sir Malcolm Morris, 786.
Venereal Diseases, the practitioner's manual of, by A. C. Magian, 31.
Wheeler's handbook of medicine, 242.
X-ray atlas of the systemic arteries of the body, by H. C. Orrin, 704.
X-ray observations for foreign bodies and their localization, by Harold C. Gage, 704.
Boorstein, Samuel W.: treatment of acute polyarthritis, 96.
Borax treatment of epilepsy, a modified, 871.
Boshouwers, Hubert M.: cesarean section vs. craniotomy, 529.
Botulism: a report of fifteen cases, in three series, 763; or lethargic encephalitis, 527; the throat in, 442.
Boulden, George Porter: parallel between dreams and psychoses, 341.
Bowel, pelvic, applied anatomy of the, 900.
Boxing, the facial traumatisms of, 274.
Boys, a twenty-four hour schedule for, 418.
Brain complications of measles, 28.
Bram, Israel: diagnostic methods in exophthalmic goiter, with special reference to, 887.
Breast feeding, a study of, in the City of Minneapolis, 418.
Breasts, supernumerary, in the axillæ (anatomical note), 438.
Brodhead, George L.: spontaneous closure of large vesicouterine fistula, 437.
Bromidrosis, 588.
Bronchi, and esophagus, a series of foreign bodies in, 827; dilatation of the, a review of forty cases observed June, 1918–June, 1919, 253.
Bronchopneumonia, grippal, profuse hemoptysis in, 707.
Browning, William: a spinal sign in gastric crises of tabes; the point of origin of such attacks, and their treatment, 728; the question of thymic epilepsy, with report of a demonstrative case, 1013.
Bubonic plague, fixation abscess in the treatment of, 317.
Buccal mucous membrane, tongue, lips and, frequency of syphilis with cancer of the, 617.
Buchanan, J. Arthur: the Mendelianism of migraine, 807.
Bullet wounds, lead poisoning from, 905.

Calcium chloride, the use of intravenous injection of, in the treatment of pulmonary tuberculosis, 503.
Calcium deficiency, many orthopedic deformities due to, 913.
Calcium-magnesium-phosphorus balance in children subject to convulsive disorders, 419.
Calculi impacted in the pelvic portion of the ureter, the treatment of, 408.
Calculus, renal, with negative *x*-ray findings, 195.
Campbell, W. A.: encephalitis lethargica, 434.

Camphor, spirits of, in hay fever and asthma, 588; subcutaneous injections of, in influenza, 378.
Cancer, a new and successful diagnosis and treatment of, 715; and marriage, 864; breast, inflamed axillary lymph nodes in nonulcerated, 703; cervical, an analysis of the failures in radium treatment of, 79; diagnosis, the aims and methods of, 200; electrochemism in the etiology and therapeusis of, 133; gastrointestinal, the blood sugar tolerance test as an aid in the diagnosis of, 285; internal, the diagnosis of, 449; intrinsic, of the larynx, 365; mortality in Great Britain, 322; of the colon, early symptoms of, 271; of the ileocecal valve, 230; of the lips, tongue, and buccal mucous membrane, frequency of syphilis with, 617; of the middle ear, symptomatology of, 399; of the omentum, 103; of the rectum, diagnosis of, 312; of the stomach, repugnance to meat in, 525; of the stomach, should, be subjected to operation? 746; of the uterus in young women, 792; of the uterus, landmarks in the treatment of, 672; of the uterus, technique of radium therapy in, 785; operable, of the cervix, operation or radium for, 79; potassium nitrate in, 569, 991; rectal, advances in surgical treatment of, 1073; rectal, resection of, in a youth of twenty, 573; rectal, the physician's rôle in the treatment of, 821; research, 246; Research Fund, work of the, 362; some factors that determine tissue resistance to, 752; the factor of fever in the diagnosis of, 156; the nature of, 443; the origin of, 785; the relation of the medical profession to the campaign for the control of, 200; the treatment of, 354, 826; uterine, radium therapy in, 121.
Canton hospital anniversary, 402.
Capsule, internal, the functional localization of the, 653.
Caput coli, dilatation and plication of the, 383.
Carbohydrates and acidosis, 740.
Carbuncles, boils and, abortive treatment of, 367.
Carcinoma, borderline, of the cervix and its treatment, 750; intrinsic, of the larynx with a second report of cases operated on by suspension and dissection, 584; of the stomach, resection for (four years ago), 664; jejunal colic fistula sequel to resection anastomosis of transverse colon for, 753; primary, of the pancreas, report of a case of, surgical jaundice, 767.
Cardiac, arrhythmia, the treatment of, 512; cases, sanatorium treatment of, 34; disease in children, the place of tonsillectomy in the management of, 919; disease, disorders of the respiratory function in, 669; disease, extent of, among children of school age in New York City, 32; efficiency, rebreathing and ergometer determinations as a method of estimating, 249; murmurs, concerning the diagnostic value of, 501; the psychology of the, and the doctor, 918; upsets, acute, occurring, during or following surgical operations, 572.
Cardiacs, sanatoria for, 33.
Cardiology, modern, 777.
Cardiospasm, a case of, 371.
Cardiovascular disease, prognosis in, with special reference to the application of graphic methods, 287; syphilitic, in the army, 34.
Cardiovasculorenal pathology, recent developments of, in France, 106.
Caries, dental, the cause of, 609.
Carotid gland, adenomata of the, 282.
Carpenter, the Wesley M., lecture, 832.
"Carrier," the meningococcus, question, 701.
Carriers, diphtheria, treatment of, with detoxicated Klebs-Loeffler vaccine, 1038.
Carter, William Wesley: nasal deformities due to the submucous operation, their prevention and their treatment, 808.
Cartilage, grafting, 692; internal semilunar, Willem's treatment following operation for, 81.
Casoni cutireaction in echinococcus disease, 367.
Castex, Mariano R., Waldorp, Carlos P., and: Rummo-Ferranini genito-dystrophic geroderma senilism, lean type, due to tardy hereditary syphilis, 1009.
Catarrh, the defensive value of normal mucus formation and the theory of, 914.
Cats, effects on, of digitalis lutea and digitalis thapsi, as noted during intravenous injection, with simultaneous electrocardiographic tracings, 250.
Cattle plague, 615, 1036; the epidemic of, 783.
Cavell, Edith, monument to, 615.
Cecostomy, appendicostomy and, a brief experience with, for intestinal stasis in epilepsy and neurasthenia, 449.
Cecum, diverticulosis of the colon, with special reference to the, 413.
Cells, red blood, the fate of subcutaneously injected, 419; the, of the arachnoid, 829.
Centrotherapy, see *Nasal Cauterization.*
Cerebral, localization, Monakow's views on, 931; softening simulating lethargic encephalitis, 409.
Cerebrospinal, fever, a summary of the results of the serum treatment of, 267; cases of, 701; fluid examination, on the clinical routine, in the diagnosis of nervous disease, 785; fluid, injections of, in cerebrospinal fever, 1037; fluid, its changes in various diseases and their significance, 414; fluid, the significance of xanthrochromia of the, with report of a case, 327.
Cerebrum, relations of the, to the sexual functions, 106.
Cerumen, hypersecretion of, in paralysis of the cervical sympathetic, 914.
Cervical sympathetic, hypersecretion of cerumen in paralysis of the, 914.
Cervix, borderline carcinoma of the, and its treatment, 750; operable cancer of the, operation or radium for, 79.
Cesarean, salpingectomy, recovery, full-time tubal pregnancy, 29; section, accidental hemorrhage, hematuria in pregnancy, 748; section, double-flap low, results, 750; section, extraperitoneal, 76; section scar, rupture of, in subsequent pregnancy and labor, 701; section vs. craniotomy, 529.
Chancre, syphilitic, the diagnosis of, of the palpebral conjunctiva, 482.
Chancroid, increasing frequency of, 30.
Chancroidal infection of a year's duration cured by specific serum, 240.
Chapin, Henry Dwight: an epidemic of kaffirpox in Jamaica, 553.
Chelidonin, a neglected alkaloid of chelidonium, or tetterwort, the pharmacology of, 913.
Chelidonium, or tetterwort, the pharmacology of chelidonin, a neglected alkaloid of, 913.
Chemotherapy, 735; and acid-fast bacilli, 906; of influenza, 745.
Chest, gunshot injuries of the, in civil practice, 784.
Chicken-pox, herpes and, 489.
Chideckel, Maurice: dreams as the cause of death and disease, 182.
Chilblains, see also *Pernio;* vaccines in the treatment of, 611.
Child, boarded-out, the medical supervision of the, 418; health centers, 858; health work in Solvay schools, 407; mentally backward, what are we doing for the, 702; mortality in the Belgian Congo, 574; the circumcised, the ulcerated meatus in the, 332; the deaf, 36; the inferiority complex in, 204; welfare, maternity and, 952.
Childhood, chronic tuberculous endocarditis in, 189; delinquency, some medical aspects of, 205; infancy and, the treatment of pyelitis in, 913; the suboxidation in, 457; the use of water in diseases of, 827.
Children, bacillary dysentery in, 408; abnormalities of the gastrointestinal tract in persistent constipation in, and the application of roentgenograms in their recognition, 830; abscess of the larynx in, 64; and young adults, the effort syndrome in, 372; chronic intestinal indigestion in, over one year old, 446; dreams in, 578; electrocardiography in, 420; extent of cardiac disease among, of school age in New York City, 32; focal infections in, 370; food requirements of, after the first year, 373; French, and the war, 229; infants and, further progress in the study of the relative efficiency of the different mercurial preparations in the treatment of congenital syphilis in as determined by a quantitative analysis of the mercury elimination in the urine, 330; infants and, pleural disease in, with special reference to empyema, 238; infants and, recent studies of blood nitrogen in, 419; infrequency of intestinal parasites in young, 71; of school age with heart disease, syphilis in, 919; papillomata of the larynx in, 357; prevention and treatment of weak-foot in, 238; school, a study of malnutrition in, 113; school, who through lack of emotional control develop habits of truancy, 205; some indications for operation on the nasal sinuses in, 585; suffering from nutritional disorders, nature of the reducing substance in the urine of, 328; syphilis of the nervous system in, 1076; the calcium-magnesium-phosphorus balance in, subject to convulsive disorders, 419; the etiology of osteosarcoma of the upper jaw in, 863; the place of tonsillectomy in the management of cardiac disease in, 919; unappreciated agencies in the defective development of, 1075; with heart disease, circulatory reactions to test exercises in, 919; women and, suicides of, increase, 275; women and, venereal disease in, 246; young, direct laryngoscopy in, 456; young, infants and, the misuse of milk in the diets of, 373.
Children's clinic, in the department of psychopathology at Cornell University, social maladjustment as seen in the, 205; the evolution of a, 127.
China, medical progress in, since the republic, 29.
Chiropractic examiners, powers of North Carolina board of, 691.
Chloroform syncope averted by direct heart massage, 150.
Chlorosis, action of iron in, 439.
Cholecystitis, recurring, 294; without stones, diagnosis and treatment of recurrent, 211.
Cholecysto-gastrostomy, the control of hyperchlorhydria and its consequences by, 476.
Cholera, the upstream spread of, 483.
Cholesterol thorax, 953.
Chorea, electric, of Dubini, acute myoclonic encephalitis and, 317; the electric, of Dubini and lethargic encephalitis, 671.
Circulation, the gravity of the resisting ability of the; its measurement and significance (blood ptosis), 956.
Circulatory system in nutritional disorders, 419.
Circumcisions, phimosis and the guillotine, a new instrument for, 1061; the guillotine, a simple one-man instrument for doing, 479.
Clapp, Herbert C.; obesity, 89.
Clark, L. Pierce: a study of the socially maladjusted, 1.
Claudication, occipital intermittent, 324.
Clubfoot, congenital, in infants, correction of, 407.
Cocaine by the mouth, recovery from fifteen grains of, 567.
Cocainomania in Brazil, 241.
Cockroach, tincture of, for asthma, 168.
Codliver oil in tuberculosis, 778.
Coffee and vitamines, 906.
Coghlan, John: the question of compulsory subscriptions, 192; unnecessary noise, 570.
Cold a disease within question as to previous medical attendance, 20.
"Colds," 671.
Colon, cancer of the, early symptoms of, 271; diverticulosis of, with special reference to the cecum, 413; mobile proximal, clinical manifestations of, 829; non-rotation of the, and its relation to appendix pathology, 83.
Compensation for inguinal hernia—attempted release of employer, 734.
Complement fixation, reaction, the, in tuberculosis, 660; test in pulmonary tuberculosis: its use as a means of diagnosis, 744.
Complex, the mental, 58.
Conflict, the mental, 145.
Conjunctiva, palpebral, the diagnosis of syphilitic chancre, 482.
Conjunctivitis, purulent, in England, 111.
Constipation, 671; in old people, 1050; persistent, in children, abnormalities of the gastrointestinal tract and the application of roentgenograms in their recognition, 830; spastic, 449.
Consumptive ex-service men, 781.
Contagious diseases, errors in the diagnosis of the, 352; summary of the morbidity from, in France during the war, 966.

Contusions, ocular, manner of production of, 315.
Convolution, frontal, the "criminal" types of, 190.
Convulsive disorders, the calcium-magnesium-phosphorus balance in children subject to, 419.
Cooperation among physicians, 999.
Cornea, ulcers of, 168.
Cornwall, Edward E.: a suggestion for a dietetic prescription blank, 185.
Correspondence, 25, 109, 153, 154, 192, 237, 404, 443, 444, 486, 528, 529, 569, 570, 740, 826, 950, 951, 991, 1033, 1034; Belgium, 236, 615, 783, 1035; Geneva, 278, 364, 531, 910, 1070; London, 25, 68, 110, 154, 193, 234, 277, 320, 362, 405, 445, 487, 529, 570, 613, 657, 697, 741, 781, 824, 867, 909, 951, 993, 1034, 1068.
Courtesy, an example in, 1065.
Crance, Albert M.: the clinical value of systematic history-taking in gallbladder disease, with corroborative surgical findings in a series of twelve illustrative cases, 260.
Cranial stigmata of heredosyphilis, 1066.
Cranioplasty (two cases), lantern slides, 753.
Craniotomy, cesarean section, vs., 529.
"Cream cakes" and the paratyphus B., 871.
Cress, Walter W.: intestinal parasites as a cause of appendicitis: report of a case, 143.
Cripplings, disuse, common motor disorders, neuroses, post-infective and others, 554.
Crises, gastric, of tabes, a spinal sign of; the point of origin of such attacks, and their treatment, 728.
Cruchet, René: the Bordeaux conception of lethargic encephalitis or epidemic encephalomyelitis, 225.
Crusades, modern, some racial problems, social evils, and, 239.
Cryptogenic infections, the anatomy, physiology, and pathology of the tonsillar structures in relation to, 593.
Crypts, retention, in the infratonsillar nodules as common and extensive harbors of pathogenic bacteria, 580.
Cryrotherapy, progress in, 526.
Culver, George D., Montgomery, Douglass W., and: eczema of the vermilion border of the lips, 141.
Current, continuous, in inflammatory conditions, 922; direct continuous, including electrolysis, electrochemical surgery, ionization and all apparatus connected therewith, 834; direct, diffusion of foreign ions into the body by the, 875; various ways of using the, in exophthalmic goiter, 873.
Currents, Arsonval on the history of high frequency, in therapeutics, 1081; high frequency, 834; high potential, their significance and the indications for their use, 875; rhythmic, 834.
Curriculum, medical, the place of preliminary science in the, 239.
Cutter, J. B.: the two classes of physicians, 154.
Cutireaction, Casoni, in echinococcus disease, 367.
Cyst, an unusual abdominal, 748; dermoid, of the mediastinum with transmitted pulsation, 1019; dermoid, of the ovary; etiology, diagnosis, and treatment, 747; lutein, accompanying hydatiform mole, 79; spermatic, the symptomatology and complications of, 987; thyroglossal, the complete extirpation of, 525.

D

Dana, Charles L.: descriptive psychology and medicine, 338, 404.
Davin, John P.: fame and professional liberty, 237; regulating the medical profession, 740; the bureau of internal revenue and the practice of medicine, 109; the late Dr. Laasé and the drug laws, 404.
Darwinism, Mendelism and, 577.
Deaf child, the, 36.
Deafened, how the, rebuild their lives, 37; man's needs and what the physician should do for him, 35; the psychology of the, from a layman's standpoint, 37.
Dearborn, George Van Ness, therapeutic information wanted, 25.
Death, and disease, dreams as the cause of, 182; disease or accident as proximate cause of, 398; fetal, the significance of syphilis in prenatal care and in the causation of, 240; late chloroform, in hepatic cases, 273; thymus, 409; under anesthesia, resuscitation in, 997; whether fall or disease proximate cause of, 356.
Deception and self-deception in the practice of medicine, 67.
Defects of hearing and speech, demonstration of reconstruction section of, 36.
Defense mechanisms, 302.
Deficiency, calcium, many orthopedic deformities due to, 913; disease, dietetics in, 819; disease, is rickets a, 746; dietetic, and endocrine activity, with special reference to deficiency edemas, 490.
Deformities, nasal, due to the submucous operation, their prevention and their treatment, 808; orthopedic, many, due to calcium deficiency, 913.
Degenerations, myocardial, and their treatment, 873; psychopathic, and disequilibrium, 318.
Delineator, roentgen-ray findings with the, in cases of pylorospasm, 884.
Delinquency, childhood, some medical aspects of, 205.
Delivery, the pathogenesis of traumatic lesion of the orbit during, 651.
Dementia precox and tuberculosis, 450; familial, 483; the effect upon the blood pressure of the injection of adrenalin in, 364; the pathogenesis of, 550; the prognosis of, 1002.
Dengue fever, the etiology of, 828.
Dental, caries, the cause of, 509; stigmata in the diagnosis of obscure congenital lues, 830.
Dermatitis, infectious eczematoid, 700.
Dermoid cyst of the mediastinum with transmitted pulsation, 1019.
Dextrose, chemically pure anhydrous, as a therapeutic agent, 973.
Diabetes a defense reaction, 14; in relation to the ductless glands, 448; insipidus, 1028; insipidus, the prognosis and complications of, 862; mellitus, control methods in the treatment of, 156; mellitus, mild, 378; the dietetic treatment of, 945; the total metabolism in, 250.
Diabetics, observations upon various types of, under the present method of treatment, 323.
Diagnosis, early, 21; the moral element in, 864.
Diaphragm, eventration of the, with report of a case, 289.
Diarrhea, hemorrhagic, due to the streptococcus mucosus, a brief case report of an epidemic of, 329; infectious, 630; pneumonia with, 440.
Diathermy, an aid in empyema, 876, 1015; and galvanism, employment of, in the management of sequelæ of occlusion, partial or complete, and of rupture of the cerebral arteries, 851; as a therapeutic agent, especially in the treatment of sprains, fractures, adhesions, and chronic stiff and painful joints, 839; treatment of fractured patella, 923.
Dickinson, G. K.: is tuberculosis contagious? 943.
Diet, influence of, on the water content of the body, 366; the, and health, 9.
Dietetic, prescription blank, a suggestion for, 185; reform, the urgent need of, and the duty of the medical profession toward all the young of the nation, 374.
Dietetics, 835; in deficiency diseases, 819.
Diets of infants and young children, the misuse of milk in the, 373.
Digitalis, clinical experience with a dried aqueous extract of, 166; in postdiphtheritic cardiac disturbances, 1065; lutea and digitalis thapsi, effects of, on cats, as noted during intravenous injection, with simultaneous cardiographic tracings, 250; strophanthin and, on certain differences in the action of, in patients, 333; therapy, some newer concepts of, 955.
Diphtheria, bacilli, cultures of, in whole coagulable blood, 284; carriers, treatment of, with detoxicated Klebs-Loeffler vaccine, 1038; the results of the use of toxin-antitoxin in immunization against, during a period of six years, 1006; wound, 619.
Disabilities, industrial, physiotherapy in the treatment of, 876.
Disease, death and, dreams as the cause of, 182; the individual factor in, 647; Thornwaldt's, 1038.
Disequilibrium psychopathic degeneration and, 318.
Dissection, suspension and, intrinsic carcinoma of the larynx with a second report of cases operated on by, 584.
Diverticulosis of the colon, with special reference to the cecum, 413.
Doctor, poetic, state medicine and the, 639; the, 412.
Doctors, the plight of Petrograd, 840.
Dogs, "sore mouth" of, pellagra and, 153.
Dogwood for labor pains, 630.
"Domestic measures," 924.
Dorland, W. A. Newman: the problem of the efficacy of topical applications of methylene-blue in female gonorrhea, 268.
Draft, selective military, lessons from the, 953.
Dreams, and psychoses, parallel between, 341; as the cause of death and disease, 182; in children, 578; "subconsciousness" and, 505.
Drueck, Charles J.: applied anatomy of the pelvic bowel, 900; diagnosis of cancer of the rectum, 312.
Drug addiction, inconclusive experiments concerning, 1033; addicts, responsibility of the state for, 1034; laws, the late Dr. Laasé and, 404; vegetable, deletions, proposed, 265.
Drugs, intravenous use of, in oil, 118.
Dubini, the electric chorea of, and lethargic encephalitis, 671.
Dubreuil-Chambardel syndrome, 745.
Duct sign, the, in mumps, 372.
Ductless gland therapy, observations upon, 323.
Ductless glands, the, 502; diabetes in relation to the, 448.
Duodenal, and gastric ulcer, a critical review of five hundred cases of, 1037; and gastric ulcers, the results of operation on, 665; dilatation, chronic, 756; ulcer, see *Ulcer;* ulcer, fluoroscopic diagnosis of, 666; ulcer, gastric and, and their surgical treatment, 836; ulcers, the site and number of, 524.
Dying declarations not admissible in civil cases before medical boards, 187.
Dyspepsia, pancreatic, and its coprological syndrome, 865; true and false, 1028.
Dyspeptic syndromes, the grand, 745.
Dyspituitarism, so-called: absorption of the membranous bones, exophthalmos and polyuria, 369.
Dysentery, bacillary, in children, 408; paratyphoid, the leucocytic reaction in a, and following vaccine inoculations, 1036.

E

Ear, a study of acute infections of the, as seen by the physician, 415; middle, symptomatology of cancer of, 399.
Ears and the job, 38.
Earths, rare, in medicine, 611.
Echinococcus disease, the Casoni cutireaction in, 367.
Eclampsia, puerperal, in hospital practice, 491.
Ectopic gestation, a case of unusual, 452; an analysis of fifty cases of, 958.
Eczema, infantile, the relation of food to, 911; of the vermilion border of the lips, 141.
Edema, chemical studies on, 250.
Edemas, deficiency, dietetic deficiency and endocrine activity, with special reference to, 490; pathology of, 325.
Efficiency, and fatigue, industrial, discussion on, 445; cardiac, rebreathing and ergometer determinations as a method of estimating, 249.
Effort syndrome in children and young adults, 372.
Egg albumin in stools, precipitins for, 373.
Einhorn, Max, and Meyer, Willy: diagnosis and treatment of recurrent cholecystitis wthout stones, 211; and Scholz, Thomas: roentgen-ray findings with the delineator in cases of pylorospasm, 884.
Eisendrath, Daniel N.: recent progress in kidney and ureteral surgery, 645.
Electrocardiography in children, 420.
Electrochemism in the etiology and therapeusis of cancer, 133.
Electrolysis, the treatment of hemorrhoids by, 921.
Electrotherapy, arthritis and, 838.
Elliott, Jabez H.: dilatation of the bronchi. A review of forty cases observed June, 1918–June, 1919, 253.

Elwyn, Herman, and Flood, Edward P.: kidney function in a case of bichloride poisoning, 56.
Emaciation, leanness and, 779; prearteriosclerotic, 956.
Emetine, cure of oriental boil by, 865.
Emphysema, mediastinal, following aspiration pneumonia, heart displacement apparently due to, 371; the causal factors for, attending bronchiolar hypertonus, 287; empyema diathermy an aid in, 876, 1015; influenza pneumonia complicated by, in an infant, 62; pleural disease in infants and children, with special reference to, 238; the treatment of, caused by pneumococci, 335; treated by Soresi's method, 663.
Encephalitis, acute epidemic, 500; acute myoclonic, and electric chorea of Dubini, 317; epidemic, 226, 804; epidemic, acute infectious myoclonus multiplex and epidemic myoclonus multiplex, 533; epidemic, relations between grippe and, 325; epidemic, the asthenia of, and of grippe, 491; epidemic, the hyperkinetic form of, 989; is lethargic, a form of rabies, 608; lethargic, 367, 409; lethargic, acute veronal poisoning simulating, 985; lethargic, and the poliencephalitis of influenza, 30; lethargic, botulism or, 527; lethargic, cerebral softening, simulating, 409; lethargic, fixation abscess in the treatment of, 523; lethargic, glycorrhacia and, 541; lethargic, in the past, 151; lethargic, or epidemic encephalomyelitis, the Bordeaux conception of, 225; lethargic, petty signs of, 324; lethargic, the electric chorea of Dubini and, 671; lethargic, syphilis and, 503; lethargic, the epidemic of, 969; lethargica, 434; lethargica, a case of chronic (residual), simulating the paralysis agitans type, in a boy of 16 years, 1020; lethargica, epidemic, 326; lethargica (epidemic encephalitis) 1079; lethargica, experimental studies in, with lantern slides, 705; lethargica, in Europe, 1066; lethargica, in Holland, 1073; lethargica, in Spain, 587; lethargica, the symptomatology of, 706; sporadic and epidemic, 573.
Encephalomyelitis, acute diffuse epidemic, 158; epidemic, the Bordeaux conception of lethargic encephalitis or, 225.
Endocarditis, chronic tuberculous, in childhood, 189; the prophylaxis of, 1029.
Endocrine, activity, dietetic deficiency and, with special reference to deficiency edemas, 490; glands, diseases of the, 872; influence, mental and physical, in women, 748; syndromes, etiopathogenesis of, 360.
Endocrines in gynecology, 869.
Endocrinology and the heart, 510.
Endometritis, cervical, a neglected form of, 77.
Enteric fever, the myth of "atypical," 954.
Enuresis, 749.
Epidemiology, industrial, 744.
Epididymitis, gonorrheal, autoserotherapy of, 275.
Epilepsy, 756; a modified borax treatment of, 871; and neurasthenia, a brief experience with appendicostomy and cecostomy for intestinal stasis in, 449; recent advances in the treatment of, 1002; thymic, the question of, with report of a demonstrative case, 1013; treated with luminal, 1037.
Epinephrin hypersensitiveness, and its relation to hyperthyroidism, 284; in hyperthyroidism, 164.
Epithelioma, metastases of a basal-cell, 778.
Equilibrium, acid base, studies of the, in disease from the point of view of blood gases, 285.
Ergometer, rebreathing and, determinations as a method of estimating cardiac efficiency, 249.
Ergotism, was the "Leper" of Grünewald a victim of, 441.
Erysipelas, anthrax mistaken for, 924; in the aged, the prognosis of, 819.
Erythema nodosum, its treatment by streptococcus vaccine, 859.
Erythemata, infectious, of typhoid fever, the diagnosis and prognosis of the, 653.
Eserine in sympathicotonus, 654.
Esophagism and allied disorders, 583.
Esophagus, a case of multiple strictures of the, cured after repeated dilatation with graduated bougies, 581; bronchi and, a series of foreign bodies in, 827; congenital atresia of the, 370.
Ether injections, treatment of whooping cough with, 359; intramuscular injections of, in pertussis, 703; treatment of peritoneal exudations by, 1036.
Ether-oil-colonic anesthesia, the toxic thyroid; its treatment by, 749.
Etiopathogenesis of endocrine syndromes, 360.
Evidence, hearsay, of physician's declarations inadmissible, 268; see also *Expert evidence.*
Evil, the roots of, 179.
Exercise, abdominal, the value of, pre- and post-partum, 791; physical, and physiology, 655; therapy, mechanical vibration and, 835.
Exercises, graduated, in cases of functional heart disturbance, 876; test, circulatory reactions to, in children with heart disease, 919.
Experiments, laboratory, to determine the value of certain agents in connection with surgical operations, a preliminary report on, 1021.
Expert evidence, admission of, as to lost *x*-ray picture, 1063; may be based on testimony heard and documents examined, 563; medical witness, competency of, how shown, 985; opinion as to effect of narcotic on creditability of witness held inadmissible, 356; qualification of, report on *x*-ray picture, 902; testimony, treatment of gunshot wounds, 563.
Ex-service men, consumptive, 781.
Extract, luteum, 748; placental, placental gland and, 912.
Exudations, peritoneal, treatment of, by ether, 1036.
Eye, conditions of interest to the general practitioner, 407; disease, focal infections in relation to, 417; injury to, by being struck by insect accidental, 1063; symptoms of mesencephalitis epidemica, narcoleptic form, 830; the injurious effects on the, of the various toxemias, 538.

F

Face surgery, 487.
Facial paralysis and Weber's syndrome, 652.
Failure to diagnose, insufficient evidence of, 480.
Fame and professional liberty, 237.
Family, an anosmic-epileptic, 737; remedies, prescribing, as a business not authorized, 902.
Fasters, the Irish, 694.
Fatigue, 618; chronic: diet, exercise, and other factors in treatment, 28; efficiency and, industrial, discussion on, 445.
Fear, the elimination of, 951.
Febriculas, the, 566.
Federation of Medical and Allied Societies, first annual meeting of, 405.
Feeding, breast, a study of, in the city of Minneapolis, 418.
Fees, physician's, under contract, industrial board has no jurisdiction to determine, 774.
Female, sterility in the; a report of operative cures, 77.
Femur, compound fracture of, 119; fracture of the, 119; fracture of the, management of, 119.
Fever, cerebrospinal, a summary of the results of the serum treatment of 267 cases of, 701; in London, 781; injections of cerebrospinal fluid in, 1037; see also *Typhoid, Acute Rheumatic,* etc.; the factor of, in the diagnosis of cancer, 156.
Field, C. Everett: the influence of radio activity in the treatment of hypertension, 1051.
Field, Cyrus W., Higley, Henry A., and: some phases of blood chemistry of practical use to the practitioner, 171.
Flea may grippe be transmitted by the, 693.
Fleiss, the, periodicity theory, 30.
Flexor longus hallucis, recovery of a needle from tendon of, 728.
Flood, Edward P., Elwyn, Herman, and: kidney function in a case of bichloride poisoning, 56.
Fluoroscope, notes on the use of the, in gastroenterology, with reports, 1043.
Focal infection, improvement in Graves' disease subsequent to severe, 534; infections in relation to eye disease, 417; infection, lymphocytosis as a diagnostic sign of, 502; infection symposium on: the hospital, the doctor, and the dentist, 417; infections in children, 370.
Follow-up system, the importance of a, 78.
Food requirements of children after the first year, 373; the relation of, to infantile eczema, 911; values in tuberculosis, some remarks on, 914.
Foot and mouth disease, is ordinary aphthous stomatitis a form of, 746.
Forceps, a review of the incidence of, in 2,000 cases, 790; operation, the prophylactic, 76.
Foreign bodies, a series of, in the bronchi and esophagus, 827; body in the right lung for five years: removal, recovery, 663.
Fibrillation and tachysystolia, quinine in, 703.
Fibroids, uterine, complicating pregnancy, 490; uterine, sarcomatous transformation of, 46.
Fibroma of the ovary, 751.
Fibrosis, arterial, hypertension and, 280.
Field, Cyrus W., Higby, Henry A., and: some phases of blood chemistry of practical use to the practitioner, 169.
Fighting fire with fire, 941.
Filaria with hydrocele (two cases), 916.
Filariasis, cutaneous, in Guatemala, 484.
Finger printing, *x*-ray, 1008.
Fire, Saint Anthony's, 402, 611.
First aid congress, an international, 361; industrial injuries and. A plea for the immediate treatment of the injured, 307.
Fischer, Louis: partial asphyxiation of an infant, resulting from the inhalation of dusting powder, 1027.
Fistula, anorectal, a discussion of postoperative recurrences of, their causes and prevention, 688; inaccessible vesicovaginal (lantern slide demonstration), 454; jejunocolic, following gastrojejunostomy, clinical observations on, 72; jejunal colic, sequel to resection anastomosis of transverse colon for carcinoma, 753; para-coccygeal, 528; spontaneous closure of a large vesico-uterine, 437.
Fitch, William Edward: the value of immunizing doses of influenza vaccine in the prophylaxis and specific treatment of influenza, 100.
Fowler, Royale H.: surgical jaundice: report of a case of primary carcinoma of the pancreas, 767; the early diagnosis of gall-bladder lesions, 898.
Fox, Howard: the treatment of alopecia areata with quartz lamps (Kroymayer and Alpine), 895.
Fracture, compound, of the femur, 119; negligence in setting, not established, 861.
Fractures, 416; of the metacarpal bones, the prognosis of, 401.
Frank, L. J.: the functions of the hospital, 193.
Freeman, Rowland G.: the use of fresh vaccines in whooping cough, 762.
Friedman, E. D.: epidemic encephalitis, 226.
Friedman, Joseph, and Greenfield, Samuel D.: an unusual case of lateral sinus thrombosis, 942.
Friends' unit finances hospital in France, 546.
Froelich's syndrome, organotherapy in, 655.
Frontal convolution, the "criminal" types of, 190.
Function, respiratory, disorders of, in cardiac disease, 669.

G

Galen's digestive philosophy, 103.
Gall-bladder affections, the diagnosis and treatment of, 112; disease, diagnosis of early, 324; disease, the clinical value of systematic history-taking in; with corroborative surgical findings in a series of twelve illustrative cases, 260; lesions, the early diagnosis of, 898; lesions, the roentgenologic diagnosis of, 1037.
Gallieni, General, the disease and death of, 966.
Gallstones, infusion of parsley in the treatment of, 588; the occurrence of, in young individuals, 702.
Galvanism, diathermy and, employment of, in the management sequelæ of occlusion, partial or complete, and of rupture of the cerebral arteries, 851.
Galvano-palpation, 1026.

Gangrene, gas, in civil practice, 360; of the penis in old men, 503; of the sulcus of the penis and scrotum due to the bacillus perfringens and septic vibrio, 737.
Gas gangrene in civil practice, 360; phlegmon, is Ludwig's angina a, 946.
Gases, blood, studies of the acid base equilibrium in disease from the point of view of, 285.
Gasserian ganglion, injection of, for trifacial neuralgia, 81.
Gastrectomy with reconstruction of physiological rapports between stomach and intestines, 663.
Gastric and duodenal ulcer, a critical review of five hundred cases of, 1037; and their surgical treatment, 836; and duodenal ulcers, the results of operation on, 665; function, an investigation of by means of the fractional test-meal, 617; hemorrhage, 842; ulcer and its treatment, 832; ulcer, see *Ulcer*.
Gastroenterology, notes on the use of the fluoroscope in, with reports, 1043.
Gastrointestinal conditions, personal experiences in the treatment of, 837; disturbances in affections of the ocular mechanism, 196; methods, a survey of, 929.
Gastrospasm and its diagnostic significance, with lantern-slide demonstration, 413.
Gaucher's disease, 156.
Gautier, Armand, death of, 714.
Gehrung pessary, 749.
Genitalia, local affections of the, of nonvenereal origin, 197.
Genito-urinary tract, diagnosis and treatment of tuberculosis of, 280.
Gentian violet in the treatment of purulent arthritis, 447.
Genu recurvatum, traumatic, report of a case in an adult, 726.
German science, bankruptcy of, 442.
Germ-plasm, the, 396.
Geroderma (senilism), Rummo-Ferranini genito-dystrophic, lean type, due to tardy hereditary syphilis, 1009.
Gestation, ectopic, a case of unusual, 452; ectopic, an analysis of fifty cases of, 958.
Gilbert, J. Allen: the psychology of the ouija board, 547.
Gill, Elbyrne G.: headache from the standpoint of the ophthalmologist and otolaryngologist, 12.
Gland, carotid, adenomata of the, 282; ductless, therapy, observations upon, 323; placental, and placental extract, 912; suprarenal, case of pheochromocytoma of the, with hypertrophy of the left myocardium, 450; therapy, vaccine and, as an aid in our practice during the past twenty months, 923; thymus, the physiology of, 149; thyroid, woman's intuition and the, 909.
Glands, bronchial, importance of, 481; ductless, 502; ductless, diabetes in relation to the, 448; endocrine, diseases of the, 872; facial, sclerosis of the, 692; suprarenal, action of the *x*-rays on the, 231.
Glaucoma, the diagnosis of, 366.
Glénard, death of, 42.
Globulin, the precipitin test for, in the arachnoid fluid in general paralysis, 913.
Glove, rubber, where the, is behind the times, 747.
Glucose tolerance test in chronic vascular hypertension, 164.
Glycorrhachia and lethargic encephalitis, 541.
Glycuronuria, 491; alimentary, the diagnosis of hepatic insufficiency by means of, 945.
Goat's milk, 966.
Goiter, exophthalmic, a study of the correlation of the basal metabolism and the pulse rate in patients with, 165; exophthalmic, diagnostic methods in, with special reference to quinine, 887; exophthalmic, ocular symptoms in, 617; some points in the diagnosis and treatment of, 324; exophthalmic, various ways of using the current in, 873; see also *Graves' disease*.
Gompertz, Louis M.: the relation of teeth to general medicine, 217.
Gonads, histology of the, in homosexual men, 997.
Gonococcus, methods of cultivating the, and of testing germicidal agents against it: preliminary note, 784.
Gonorrhea, anorectal, 198; female, the problems of the efficacy of topical applications of methylene-blue in, 268; of the lower genitourinary tract in women, 996; some observations on the treatment of, with detoxicated vaccine, 489; therapy of, 535; when is, cured? 659.
Goodman, Herman: notes on venereal disease control, 559.
Gordon, Alfred: pure aphasias à propos of a case of pure alexia, 1059.
Gorgas, General, memorial services to, at St. Paul's Cathedral, 277; tribute at bier of, 320.
Gottlieb, A.: prostatic backache, 144.
Grafting, cartilage, 692; esthetic, of scalp, 29.
Grancher's disease, 402.
Granuloma malignum, diagnosis of, 865.
Graphic methods, prognosis in cardiovascular disease with special reference to the application of, 287.
Graves' disease, a contribution on blood pressure in, 870; improvement in, subsequent to severe focal infection, 534; see also *Goiter*.
Greenberg, David: concerning the treatment of influenza, 60.
Greenfield, Samuel D., Friedman, Joseph, and: an unusual case of lateral sinus thrombosis, 942.
Grippe, may, be transmitted by the flea? 693; relations between, and epidemic encephalitis, 325; the asthenia of epidemic encephalitis and of grippe, 491.
Grossman, Jacob: subluxation of the head of the radius, based on the study of thirty-seven cases, 981.
Grossman, Morris: iodoform poisoning, 772.
Group study in the surgery of the head, 71.
Guillotine, phimosis and the, a new instrument for circumcision, 1061; the, a simple one-man instrument for doing circumcisions, 479.
Gunshot injuries of the chest in civil practice, 784; wounds, see *Wounds*.
Guyon, Felix, death of, 840.
Gwathmey, James T., and Tibbets, E. S.: a preliminary report on laboratory experiments to determine the value of certain agents in connection with surgical operations, 1021.
Gynecological diagnosis, errors in, due to misplaced organs, 77; problem in industrial medicine, 77.
Gynecology and obstetrics, recent progress in, 275; endocrines in, 869.

H

Hairs, occurrences of, in supernumerary nipples, 282.
Hale, H. E.: dermoid cyst of the mediastinum with transmitted pulsation, 1019.
Hall of Fame, Benjamin Rush for the, 110; medical men in the, 67.
Hallucinations, erotic, 776.
Hand washing, soaps and their relation to, 281.
Hannah, Louis: status of the luetin test, 522.
Hardenbergh, Daniel B.: hypothyroidism—twenty-six years' supplemental thyroid feeding, 1054.
Harrison act, aiding and abetting violation of, by issuing prescription, 818.
Harrower, Henry R.: hypothyroidism, infiltration, and hypertension, 854; the principles of adrenal support, 391.
Hay fever and asthma, allergy, anaphylaxis, and immunity in, 216; and asthma, diagnostic tests in, 238; asthma and, observations on, 1045; and asthma, spirits of camphor in, 588.
Head, group study in the surgery of the, 71.
Headache from the standpoint of the ophthalmologist and otolaryngologist, 12; spinal puncture, new procedure for the prevention of, 598.
Healing, delayed, syphilis as a cause of, in the non-infected abdominal incision, 700.
Health, cash premium on, 557; center bill, 1077; centers, child, 358; insurance act, national, 243; insurance act, national, some medical aspects of, 658; insurance, national, 445, 741; insurance, national, the pharmaceutical aspects of, 521; international, 951; ministry of, the annual report of the chief medical officer of the, 993; national, a constructive policy of, 26; of London, 320; of the peoples, the League of Nations and, 909; public, rates and, 1035; some work of the ministry of, 657; statistics, some Spanish, 55; strikes and, 909; the diet and, 9; work, child, in Solvay schools, 407.
Hearing and speech, defects of, demonstration of reconstruction section of, 36.
Heart, acute dilatation of the, so-called, occurring during and following surgical operations. Its mechanism and management, 163; acute psychoses in diseases of the, 249; and liver, disturbances of, caused by low grades of astigmatism, 617; disease, circulatory reactions to test exercises in children with, 919; conditions, congenital and acquired, which give rise to symptoms; their significance and treatment, 173; disease, etiological classification of, 605; disease, incidence of, in adults, 32; disease, increasing athletics and, 439; disease, on the passive mechanical factor in, 157; disease, syphilis in children of school age with, 919; displacement apparently due to mediastinal emphysema following aspiration pneumonia, 371; disturbances, functional, graduated exercises in cases of, 876; endocrinology and the, 510; irregularities: their clinical recognition and interpretation, 411; massage, direct, chloroform syncope averted by, 150; patients, a report of one thousand, subjected to a complete cardiac examination, with an account of the therapeutic results, 508; patients, report of one thousand, subjected to complete examination with important therapeutic results, 537; study, practical methods of, and their relative values, 345; the, in influenza, with electrocardiographic studies, 286.
Heat regulation, metabolism and, a study of, in pulmonary tuberculosis, 669.
Hemangioma and lymphangioma, their response to the injection of boiling water, 519.
Hematocele, an infected, containing bony elements, 790.
Hematuria in pregnancy; accidental hemorrhage; cesarean section, 748.
Hemiplegia, infantile spastic, of heredosyphilitic origin, 947.
Hemoglobin content of the blood, diurnal variations in the, 701.
Hemolysis, in hemolytic anemia, one factor in the mechanism of, 829.
Hemolytic streptococci, a biological study of, from throats of patients suffering from scarlet fever, 240.
Hemophilia in women, 861.
Hemoptysis, profuse, in grippal bronchopneumonia, 707; quinine in the treatment of, 313.
Hemorrhage, accidental; cesarean section; hematuria in pregnancy, 748; essential uterine, 414; cholemic, 492; following the operative treatment of internal hemorrhoids, 323; gastric, 842; into the pelvic cavity other than those of ectopic pregnancy, 77; uterine, radium in, 684; uterine, the interpretation and clinical significance of, 43.
Hemorrhoids, internal, hemorrhage following the operative treatment of, 323; the treatment of, by electrolysis, 921.
Hemostatic, the roentgen ray as a, 271.
Hepatic cases, late chloroform death in, 273; insufficiency, 325; insufficiency, the diagnosis of, by means of alimentary glycosuria, 945.
Heredity, what governs, 529.
Heredosyphilis, cranial stigmata in, 1066.
Hernia cases, requirements of proof in, 650; direct; epigastric, case of pyloric ulcer with symptoms that might be ascribed to an existing, 664; inguinal and femoral, an operation for the radical cure of, 324; inguinal, compensation for—attempted release of employer, 734; of the ileum through a rent in the mesentery, 748; pudendal, operated by the abdominal route, 957.
Herpes and chicken-pox, 489.
Hiccough, persistent, benzyl benzoate in, 146.
Highman, Walter J.: the treatment of syphilis, 477.
Higley, Henry A., and Field, Cyrus W.: some phases of blood chemistry of practical use to the practitioner, 169.
Hip, shoulder and, certain fundamentals in the treatment of, 917.
Hirsh, A. B.: diathermy an aid in empyema, 1015.

Hirschberg, Leonard Keene: simple everyday science about yeast, 732.
Histology, historical notes on, 714.
History, some, a threat and its fulfillment, 1022.
History-taking in gall-bladder disease, the clinical value of systematic; with corroborative surgical findings in a series of twelve illustrative cases, 260.
Hodgkin's syndrome, two cases of, in Bahia, 830.
Hoffman, Frederick L.: the pharmaceutical aspects of national health insurance, 521.
Holmes, Bayard: the pathogenesis of dementia precox, 550.
Homosexual men, histology of the gonads in, 997; the male, as a social peril, 821.
Hornstine, Nathan H.: duodenal ulcer, its early diagnosis and treatment, 348.
Hospital, American, in London, 111; Canton, anniversary, 402; charitable, not liable for injuries to pay patient, 985; dinners, 825; infants', further development of, 372; isolation, function of, 1073; records admissible as evidence though bearing on liability and personal injuries, 270; records as evidence, 187, 314; right of, to refuse to allow physician of another school to practice therein, 523; the functions of the, 63, 193; treatment under statute provisions, 944.
Hospital's care, question of, in safeguarding delirious patients, 398.
Hospitals are supported by lotteries, 367; bequests to, 650; municipal, 615; rate aided, 570; the future of, 698;
Huegeli, A. G.: vaccines in general practice, 813.
Humphrey, John Freeman: a study of the natural Saratoga-Nauheim baths at Saratoga, N. Y., 262.
Hutchinson, a fourth symptom added to the triad of, 1027.
Hydatidiform mole, lutein cysts accompanying, 79.
Hydrocele, filaria with (two cases), 916.
Hyperchlorhydria, 713; some aspects of, with special reference to the treatment of this affection, 494; the control of, and its consequences by cholecysto-gastrostomy, 476.
Hyperglycemic reaction, the, 104.
Hypernephroma, results of operative treatment of, 30.
Hyperparotidia, 989.
Hypertension and arterial fibrosis, 280; arterial, treatment of, 743; chronic vascular, glucose tolerance test in, 164; hypothyroidism, infiltration and, 854; the influence of radioactivity in the treatment of, 1051; vascular, the ultimate prognosis in, 501.
Hyperthyroidism, diagnosis and treatment of, 364; epinephrin hypersensitiveness and its relation to, 284; epinephrin hypersensitiveness, test in, 164; the therapy of, 431; tuberculosis and, differential diagnosis of, 914.
Hypertonus, bronchiolar, the causal factors for emphysema attending, 287.
Hypertrophy, mammary, cured by injection of milk, 356.
Hypophrenia, influenza and, 744.
Hypophysis, radiation of the, for bronchial asthma, 661; the *x*-ray treatment of tumors of the, 986.
Hypothetical question, propriety of allowing, rests with court, 691; statements in proofs of loss on accident policy—use in, 691.
Hypothyroidism, infiltration, and hypertension, 854; twenty-six years' supplemental thyroid feeding, 1054.
Hysterectomy, ovarian function following, 366; some indications for, 751; total, advantages and technique of, 793.
Hysteria, instinct and, 157.

I

Icterus, treatment of, by sweetened urotropin, 450.
Idiopathies, toxic, an address on, 408.
Ileocecal valve, cancer of the, 230.
Ileum, hernia of the, through a vent in the mesentery, 748.
Ileus, medical treatment of, 441.
Immunity, allergy, anaphylaxis and, in hay fever and asthma, 216; post influenzal, 703.
Impaction, sigmoid—its significance, pathology, and treatment, 837.
Incision, noninfected abdominal, syphilis as a cause of delayed healing in the, 700.
Indigestion, chronic intestinal, in children over one year old, 446.
Individual factor, the, in disease, 647.
Indol test on the spinal fluid for rapid diagnosis of influenzal meningitis, 996.
Industrial disabilities, physiotherapy in the treatment of, 876; chair of, at St. Mary's Hospital, London, 782.
Industries, psychology in relation to, 579.
Infancy and maternity, a bill for the protection of, 1030.
Infant, partial asphyxiation in an, resulting from the inhalation of dusting powder, 1027.
Infants, correction of congenital clubfoot in, 407; and children, further progress in the study of the relative efficiency of the different mercurial preparations in the treatment of congenital syphilis in, as determined by a quantitative analysis of the mercury elimination in the urine, 330; and children, pleural disease in, with special reference to empyema, 238; and children, recent studies in blood nitrogen in, 419; and young children, the misuse of milk in the diets of, 373; normal, the feeding of, 765; some observations on the role of certain anaërobes in the intestinal flora of infants, 373; young, habitual vomiting in, 1050.
Infants' hospital, further development of, 372.
Infancy and childhood, the treatment of pyelitis in, 913.
Infantilism, pancreatic, 661.
Infarcts, multiple, of the skin and subcutaneous tissue, streptococcic angina with purpura hemorrhagica and, in a child two years old; healing under Dakin's solution, 371.
Infections, acute, diagnostic significance of nerve symptoms in, 365; acute respiratory, the bacteriology of the, not including the pneumonias, 1003; chronic tonsillar, 590; cryptogenic, the anatomy, physiology, and pathology of the tonsillar structures in relation to, 593; experimental, the blood alkali reserve with, 828; focal, improvement in Graves' disease subsequent to severe, 534; focal, in children, 370; focal, in relation to eye disease, 417; focal, lymphocytosis as a diagnostic sign of, 502; focal, symposium on: the hospital, the doctor, and the dentist, 417; intestinal, with lamblia duodenalis, 622; streptococcic, transference of, from foot to face, 691; venereal, present methods for limiting, 788.
Inferiority complex, the, in the child, 204.
Infiltration, hypothyroidism, hypertension and, 854.
Inflammatory conditions, the continuous current in, 922.
Influenza, a society for the study of, 504; abdominal symptoms in, simulating an acute surgical lesion, 365; and hypophrenia, 744; and sleeping sickness, 17; and the *x*-ray, 654; aural aftermaths of, the, 810; bacillus, experiments with the, 251, 670; chemotherapy of, 745; concerning the treatment of, 60; epidemiology and etiology of, 112; further studies on, 251; in England and Wales, the death rate of, 277; lethargic encephalitis and the poliencephalitis of, 30; meningitis, 1005; pneumonia complicated by empyema in an infant, 62; some cases of thrombophlebitis during the puerperium following, 751; Spanish, in the Sahlgren hospital, 240; subcutaneous injections of camphor in, 378; the blood in, 102; the heart in, with electrocardiographic studies, 286; the value of minimizing doses of influenza vaccine in the prophylaxis and specific treatment of, 100; tuberculosis and, 498; will have the flu again? No, 573.
Influenzal pneumonia, 566.
Inhibition, psychic, of menstruation, 274.
Injection, intravenous, of calcium chloride in the treatment of pulmonary tuberculosis, the use of, 503.
Injuries, industrial, and first aid, a plea for the immediate treatment of the injured, 307.
Injury due to trauma, different theories of, not inconsistent, 944; negligence and evidence of causal connection between, 20.
Inoculations, vaccine, the leucocytic reaction in a paratyphoid dysentery and following, 1036.
Insanity, mastoidectomy followed by, 28; produced by narcotics, hypothetical question as to, 438.
Insignia, new, for the medical department, 568.
Instinct and hysteria, 157.
Insufficiency, hepatic, 325; hepatic, the diagnosis of, by means of alimentary glycosuria, 945; pluriglandular, case of, 746; stenosis and, tricuspid, 953.
Insurance, accident and sickness; "confinement within the house," 650; life, the relationship of the anemias to, 533; see *Health insurance*.
Intelligence, standards of, 693.
International Surgical Society, all German, Austrian, and Turkish Surgeons expelled from the, 443.
Interne, lo, the poor, 988.
Internist, the: his duty to the public, to his patients, and to himself, 417.
Intestinal anastomosis, healing of end-to-end, with especial reference to the regeneration of blood vessels, 618; flora of infants, some observations on the role of certain anaërobes in the, 373; infection with lamblia duodenalis, 622; membranes, vividiffusion with, 649; obstruction, acute: a study of a second series of cases from the Massachusetts General Hospital, 489; obstruction, the cause of the continued high mortality in, 416; toxemia, benign mammary tumors and, 751.
Intoxicating beverage, what is an, 976.
Intoxication, bacterial, 447.
Intravenous injection of calcium chloride, the use of, in the treatment of pulmonary tuberculosis, 503; use of drugs in oil, 118.
Intuition, woman's, and the thyroid gland, 909.
Intussusception in typhoid fever, 481.
Iodoform poisoning, 772.
Ions, diffusion of foreign, into the body by the direct current, 875.
Ipecac sensitization and bronchial asthma, 784; small doses of, in the digestive disorders of bottle-fed babies, 535.
Iritis, diagnosis and treatment of, 1000.
Iron in chlorosis, action of, 439.
Irritability and stimulation, 288.
Itch, filarian, 736.

J

Jacobi, Dr. Abraham, the life and influence of, 167; presentation to the New York Academy of Medicine of a bas-relief of, 166.
Jaundice, fatal postarsphenamine, 660; post-salvarsan, 196; surgical: report of a case of primary carcinoma of the pancreas, 767.
Jaw, upper, osteosarcoma of the, in children, etiology of, 863.
Joint lesions, the present treatment of, 1036; traumatic, the pathology of, 903.
Joints, mobilizations in injured, infected, and fractured, 380.
Jones, Edward G.: surgery of the neck, 386.
Jones, Howard: vaccines for whooping cough, 950.
Josephson, Emanuel M.: protein shock reaction in leprosy, 607.

K

Kaffirpox in Jamaica, an epidemic of, random notes of a tourist, 553.
Kahane, Max: galvano-palpation. A method of detecting the presence of internal diseases by means of the galvanic current, 1026.
Kantor, John L.: a survey of gastro-intestinal methods, 929.
Kidney and ureter, abdominal pain in diseases of the, 870; and ureteral surgery, recent progress in, 645; decapsulation of, in subacute nephritis, 1073; function, in a case of bichloride poisoning, 56; in pulmonary tuberculosis, 862; sarcoma of the, 370.
Kilduffe, Robert A.: meningitis serosa, 984.
Kindred, Dr. J. J., elected to congress, 1067.
Kitchen, J. M. W.: reporting progress relating to improving the milk and butter supplies, 486.

Kleinberg, S.: traumatic genu recurvatum: report of a case in an adult, 726.
Knee-jerk test, a method for standardizing the, and its measurement, 982.
Knopf, S. Adolphus: artificial pneumothorax, 444; Benjamin Rush for the Hall of Fame, 110.
Koch, William F.: a new and successful diagnosis and treatment of cancer, 715.
Konkle, W. B.: the roots of evil, 179.
Korsakoff's disease, so-called, who was the first to describe, 574.
de Kraft, Frederic, Titus, Edward C., and: employment of diathermy and galvanism in the management of sequelæ of obstruction, partial or complete, and of rupture of the cerebral arteries, 851.
Kroymayer lamp, see *Lamp, quartz.*

L

Laasé, the late Dr., and the drug laws, 404.
Labor, analgesia and anesthesia in, 75; induction of, at term, 75; induction of, by an unusual method, 455; induction of, indications and methods, with special reference to the use of pituitary extract, 75; pains, dogwood for, 630; premature, the induction of, 828; rupture of the bladder during, 747; rupture of the uterus during, pathology and treatment, 905.
Laboratory activities in South America, 966.
Labyrinthine reactions of experienced aviators, 197.
Lactic acid milk, a brief report on, 374.
Laennec, the visit of, to Bordeaux in 1824, 672.
Lake, George B.: supernumerary breasts in the axillæ (anatomical note), 438.
Lamblia duodenalis, intestinal infection with, 622.
Lamps, quartz (Kroymayer and Alpine), the treatment of alopecia areata with, 895.
Landsman, Arthur A.: a discussion of post-operative recurrences of anorectal fistula, their causes and prevention, 688.
Lannelongue, monument to, 1008.
Laryngitis, tuberculous, and the tuberculosis problem, indifference of the laryngologist toward, 281.
Laryngologist, indifference of the, toward tuberculous laryngitis and the tuberculosis problem, 281.
Laryngopharynx, acute abscess of the lateral wall of the, 587.
Laryngoscopy, direct, in young children, 456.
Larynx, abscess of, in children, 64; and trachea, treatment of postdiphtheritic stenosis of the, 282; intrinsic cancer of the, 365; intrinsic carcinoma of the, with a second report of cases operated on by suspension and dissection, 584; papillomata of the, in children, 357; tuberculosis of, the treatment of, 503.
Laveson, H.: anxiety neurosis, 925; defense mechanisms, 302; the mental complex, 58; the mental conflict, 145; the unconscious, 599.
Lavoisier's chemistry, early American edition of, 84.
Lead poisoning from bullet wounds, 905; in the urine in neurocirculatory disturbances, 869.
League of Nations, the, and the health of the peoples, 909.
Leanness and emaciation, 779.
Legal medicine, institute of, in Geneva, 911.
Legislation, medical, needed, 491.
Leiner, Joshua H.: a case of chronic (residual) encephalitis lethargica, simulating the paralysis agitans type, in a boy of 16 years, 1020.
Lemchen, B.: the blood in influenza, 102.
Leontiasis ossea, a case of, 1017.
"Leper," was the, of Grünewald, a victim of ergotism, 441.
Leprosy, protein shock reaction in, 607.
Lesion of orbit, traumatic, during delivery, the pathogenesis of, 651.
Lethargic encephalitis, see *Encephalitis.*
Leucemia, splenic, associated with pregnancy, 750.
Leucorrhea, chronic: its pathology and treatment, 29; pathological, and its treatment, 749.
Levinsohn, Sandor A.: erythema nodosum: its treatment by streptococcus vaccine, 859.
Lewis-Benedict method, studies on blood sugar: the effect of blood on picrate solutions; a consideration of the limitations of the, 326.
Liability, extent of, 480; for injuries caused by using defective *x*-ray machine, 818.
Liberty, professional, fame and, 237.
License, revocation of, a state statute authorizing, without notice and hearing held invalid and unconstitutional, 438.
Licenses, right to practise a valuable property right—powers of board of medical examiners to suspend, 691.
Lichen planus, zonifugal, the etiology and pathogenesis of, 564.
Lichenification, lichens and, 629.
Lichens and lichenification, 629.
Life insurance, the relationship of the anemias to, 533.
Light penetration, experiments in, 836; ultra violet, as a medical adjuvant, 922.
Lingual ulcers, the differential diagnosis of, 63.
Linitis plastica and its clinical syndromes, 988.
Lips, eczema of the vermilion border of the, 141; tongue and buccal mucous membrane, frequency of syphilis with cancer of the, 617.
Lister memorial fund, 363.
Liver and biliary tract, some interesting surgical conditions of the, 747; causation and pathology of atrophy of, 871; heart and, disturbances of the, caused by low grades of astigmatism, 617.
Lobell, A.: influenza pneumonia complicated by empyema in an infant, 62.
Localization, cerebral, Monakow's views on, 931; functional, of the internal capsule, 653.
Lotteries, hospitals are supported by, 367.
Love, George R.: an accurate and simple method of testing the coagulation time of blood, 436; vividiffusion with intestinal membranes, 649.
Luckie, J. B.: allergies in chronic diseases, 733.
Ludwig's angina, is, a gas phlegmon?, 946.
Lues, obscure congenital, dental stigmata in the diagnosis of, 830.
Luetin test, status of the, 522.
Luminal, epilepsy treated with, 1037.
Lung, aorta and, a study of the progressive changes in the, as shown by *x*-ray in tuberculosis and syphilis, 499; nontuberculosis, changes following pneumonia, 1037; mapping by the injection of bismuth mixtures in the living, 585; right, foreign body in the, for five years; removal, recovery, 633.
Lungs, refinement in methods of auscultation of the, by electrical means, 247.
Lutein cysts acompanying hydatiform mole, 79.
Luteum extract, 748.
Lymphadenitis, mesenteric, 770.
Lymphangioma, hemangioma and, their response to the injection of boiling water, 519.
Lymph nodes, enlarged mesenteric, 659; nodes, inflamed axillary, in nonulcered breast cancer, 703.
Lymphocytosis as a diagnostic sign of focal infection, 502.
Lymphosarcoma, a case of, 371, 624.
Lynch, Charles: prevention of respiratory diseases, 799.
Lynch, Jerome M.: some fundamental principles underlying intestinal and rectal surgery, 432.

M

MacDonald, Arthur: the study of man after death, 219.
Macht, David I.: on the use of benzyl benzoate in persistent hiccough, 146.
McLean, Stafford: the feeding of normal infants, 765.
MacLeod, Ernest: acute veronal poisoning simulating lethargic encephalitis, 985.
McWilliams, Clarence A.: mobilizations in injured, infected, and fractured joints, 380.
Maher, Stephen H.: how "tuberculosis schemes" fail, and why, 968.
Maladjusted, socially, a study of the, 1.
Maladjustment, social, as seen in the children's clinic in the department of psychopathology at Cornell University, 205.
Malaria, algid, the diagnosis and treatment of, 496; in England, 531; in the Balkans, 241; recurrent, notes on the treatment of, by novarsenobenzol, 660; science and practice in the fight against, 914; the problem of, 986.
Male homosexual, the, as a social peril, 821.
Malignancy, the management of, by combined methods, 815.
Malignant disease of the upper air tract, results of treatment of by radiation, 581; disease, see also *Cancer;* disease, the rôle of radium needles in the treatment of, 874; growths of the uterus, röntgen therapy of, 785.
Malingerer, the problem of the, 71.
Mallory, William J.: the practice of medicine as a vocation, 891.
Malnutrition from underfeeding in a two and one-half year old child, 181; in school children, a study of, 113.
Malpractice, failure to diagnose correctly not necessarily, 356.
Malt soup extract, has, an antiscorbutic value, 417.
Mammary hypertrophy cured by injection of milk, 356; tumor, benign, and intestinal toxemias, 751.
Mammalogy—an anatomical and toxonomic consideration of the group to which man belongs, 421, 674.
Man, anthropology of modern civilized, 282; the, and the hour, 64; the study of, after death, 219.
"Man-insect-bacterium" complex, the, 336.
Mandible, fractured, bone-grafting of the, 239.
Maniacs, asthenics and, oscillometry in, 492.
Mann, R. W., Anderson, H. B., Sharpe, N. C., and: chronic tonsillar infections, 590.
Manslaughter in second degree through culpably negligent treatment of person unlicensed to practise, 774.
Marriage, amenorrhea and, 983; cancer and, 864.
Marriages, uncle-niece, 126.
Marshall, Henry Rutgers: "subconsciousness" and dreams, 505.
Massage, direct heart, chloroform syncope averted by, 150.
Mastoidectomy followed by insanity, 28.
Maternity and child welfare, 952; infancy and, a bill for the protection of, 1030, 1066; normal, in a myxedematous woman, 335.
Matter, the unity of, science and, 777.
Measles: brain complications, 28.
Measurements, physical, the value and interpretation of some, 828.
Measures, domestic, 924.
Meat, repugnance to, in cancer of the stomach, 525.
Meatus, the ulcerated, in the circumcised child, 332.
Mechanisms, nervous and mental: the nerve impulse, 17.
Mediastinum, dermoid cyst of the, with transmitted pulsation, 1019.
Medical attendance, false statements to medical examiner as to, 438; college, first, in China, 872; curriculum, the place of preliminary science in the, 239; department, new insignia for, 568; examiner's report, State statute making, conclusive only applies after policy is issued, 356; journal, first, in Palestine, 275; legislation needed, 491; men and miners, 782; men in the Hall of Fame, 67; men, the earliest, in ancient Rome and Italy, 273; practice, present trends in, 998; profession, the duty of the, toward all the young of the nation, the urgent need of dietetic reform and, 374; profession, the problem of the ailing, and its solution, 514; progress in China since the republic, 29; school at Porto Alegre, Brazil, 511; school of French West Africa, 42; study in London, post-graduate, America and, 781; supervision of the boarded-out child, 418; system, the Irish, 615; testimony as to surgeon's care and skill admissible, 480; text-books, reading, on cross-examination, 861; women's federation, first meeting of the London Association of, 1034.
Medicine, an address on the unity of, 996; deception and self-deception in the practice of, 67; descriptive psychology and, 338, 404; industrial, chair of, at St. Mary's Hospital, London, 782; industrial, gynecological problem in, 77; legal, institute of, in Geneva, 910; military, and

pharmacy, international congress of, 1035; practising without certificate, 607; practising without a license—separate offences—insufficiency of verdict — employment by another physician, 607; rare earths in, 611; relation of physiology to, 578; state, and the poetic doctor, 639; the practice of, as a vocation, 891; unlawful practice of, 314; women in, 825.
Medicolegal institute at Bucharest, 546; notes, 20, 147, 187, 270, 314, 356, 398, 438, 480, 523, 563, 607, 650, 691, 734, 774, 818, 861, 902, 944, 985, 1063.
Membranes, intestinal, vividiffusion with, 649.
Men, homosexual, histology of the gonads in, 997.
Mendelian theory, the, 577.
Mendelianism, the, of migraine, 807; and Darwinism, 577.
Meningitis due to frontal sinus suppuration with a report of three fatal cases, 587; influenza, 1005; influenzal; indol test on the spinal fluid for rapid diagnosis of, 996; meningococcus, intravenous and intraspinous treatment of, 323; serosa, 984.
Meningococcus "carrier" question, the, 701.
Menopause, venous states in, 114.
Menstrual function, conservation of the, 28.
Menstruation, new aspects of, 912; psychic inhibition of, 274.
Mental complex, the, 58; diseases, clinics for, 952; disease, the use of the thermometer in, 869; conflict, the, 145; diseases, etiology and treatment of, with special reference to the general practitioner's duty in prophylactic work, 417.
Mercur, William H.: tissue acidosis vs., blood acidosis, 467.
Mercurial preparations, further progress in the study of the relative efficiency of the different, in the treatment of congenital syphilis in infants and children, as determined by a quantitative analysis of the mercury elimination in the urine, 330.
Mercury, anaphrodisia from, 65.
Mesencephalitis epidemica, narcoleptic form, eye symptoms of, 830.
Metabolism and heat regulation in pulmonary tuberculosis, a study of the, 669; basal, a clinical apparatus for measuring, 743; basal, a study of the correlation of the, and the pulse rate in patients with exophthalmic goiter, 165; basal, determination of rate of, in thyroid disease, 1073; basal, studies in, 407; the total, in diabetes, 250.
Metacarpal bones, the prognosis of fractures of, 401.
Metastases of a basal-cell epithelioma, 778.
Metasyphilis, a new treatment of, 606.
Methemoglobin, the formation and fate of, in pneumococcus septicemia, 334.
Methemoglobinemia, bacillus aerogenes septicemia with, following abortion, 452.
Methylene blue and roentgen ray, actinomycosis treated with, 996; in female gonorrhea, the problem of the efficacy of topical applications of, 268; the therapeutic use of, 905.
Metritis, peurperal, chronic forms of, 947.
Meyer, Willy, Einhorn, Max, and: diagnosis and treatment of recurrent cholecystitis without stones, 211.
Mid-brain, lesions in the; report of a case, 332.
Midwives and woman practitioners of medicine in ancient and medieval Rome, 1008.
Migraine, 240, 756; the Mendelianism of, 807.
Milk as a source of infection, 868; and butter supplies, reporting progress relating to improving the, 486; frozen, 458; goats, 966; injections, parenteral, 188; injections, parenteral protein treatment of arthritis, with special reference to; its relation to anaphylaxis, 47; lactic acid, a brief report on, 374; mammary hypertrophy cured by injection of, 856; supply, the call for an improved, in Great Britain, 910; the misuse of, in the diets of infants and young children, 373.
Minor patient's parents, warning, of infectious disease, 20.
Mission, the failure of a, 230.
Mitral stenosis, the pathogenesis of paralysis of the left recurrent nerve in, 272.
Mole, hydatiform, lutein cysts accompanying, 79.
Monakow's views on cerebral localization, 931.
Mongolism, 492.
Monkeys, preliminary observations on the pathogenicity for, of the bacillus abortus bovinus, 331.
Montgomery, Douglass W., and Culver, George D.; eczema of the vermilion border of the lips, 141; Rabelais in libraries, 269; Rabelais' remarks on the throat, 561; ripe olives, 19.
Moral element, the, in diagnosis, 864.
Moriarta, Douglas C.: radium in uterine hemorrhage, 684.
Morris, M. Ford, Jr.: the therapy of hyperthyroidism, 431.
Motility, notes on, 296.
Motor disorders, common, disuse, cripplings, neuroses, post-infective and others, 554.
Mouth diagnosis from a dentist's viewpoint, 916.
Mucus formation, normal, the defensive value of, and the theory of catarrh, 914.
Mumps, orchitis in, 699, 743; the duct sign in, 372.
Murmurs, cardiac, concerning the diagnostic value of, 501.
Muscle re-education, the place of, in the treatment of anterior poliomyelitis (infantile paralysis), 785.
Muscles, respiratory, a case of paralysis of the, 370.
Myocardial degenerations and their treatment, 873.
Myoclonus multiplex, and acute infections, and epidemic myoclonus multiplex (epidemic encephalitis), 533.
Myopia, the prevention of, 579.
Myxedema, diagnosis of, 496; treatment of, 871.
Myxosarcoma, rapidly spreading malignant, with generalized metastases a case of priapism resulting from, 372.

N

Names, anatomical, a plea for simple, 617.
Nammack, Charles Edward: arteriosclerosis: the three-fold menace of the present day, 757.
Narcotic drugs in hospital and private practice, 1072; drugs, expert opinion as to effect of, on creditability of witness held inadmissible, 356.
Nasal cauterization (centrotherapy), neurasthenia: its treatment by, 73; deformities due to the submucous operation, their prevention and their treatment, 808.
Nathan, D.: alcohol: its status quo ante, never!, 186.
Nausea and vomiting in pregnancy, 252.
Neck, surgery of the, 386.
Needle, recovery of a, from tendon of flexor longus hallucis, 728.
Negligence, admission of, admissible in evidence, 314; and injury, evidence of causal connection between, 20; in setting a fracture not established, 861.
Neoplasms, action of uranium salts on, 484.
Nephrectomy, progress in, 828.
Nephritis, acute, prognosis in, 107; an epidemic of, 703; decapsulation of the kidney in, 1073; idiopathic, an experimental study on the origin of, 660; uremic, pernicious anemia in, 574.
Nephrosis, chronic, ultimate results in the treatment of, with the high protein diet, 116.
Nerve impulse, the, nervous and mental mechanisms, 17; injury, results of operations for, at the Edinburgh War Hospital, 745; left recurrent, the pathogenesis of paralysis of the, in mitral stenosis, 272; symptoms in acute infections, diagnostic significance of, 365.
Nerve-root symptoms simulating visceral diseases, spondylitis and abdominal pain, with a discussion of, 28.
Nerves, peripheral, discussions on the end-results of injuries to the, treated by operation, 745.
Nervous diseases, an address on the causes of, 913; diseases, chronic, therapeutic agents in, 113; disease, on the clinical value of routine cerebrospinal fluid examination in the diagnosis of, 785; system, the early signs of disease of the, 684.
Neuralgia, nasociliary, 582; trifacial, injection of the gasserian ganglion for, 81; trigeminal, the role of deep alcoholic injections in the treatment of, 365.
Neuralgias, trigeminal, the major, and their significance based on experience with 332 gasserian operations, 448.
Neurasthenia, epilepsy and, a brief experience with appendicostony and cecostony for intestinal stasis in, 449; its treatment by nasal cauterization (centrotherapy), 73; relations of, to the psychoses, 274.
Neurasthenics and nosomaniacs, 661.
Neuritis due to autointoxication, 1050.
Neurocirculatory disturbances, lead in the urine in, 869.
Neuroses, common disorders, disuse cripplings, post-infective and others, 554; gastric, 573.
Neurosis, anxiety, 925.
Neurosyphilis, intracistern injections of salvarsanized serum in, 783; results in the treatment of, 700.
Neurotomy, retrogasserian, 616.
Nevo-encephaloma, 1030.
Nice, Charles M., and Vance, J. G.: etiological classification of heart disease, 605.
Nightmare and pavor nocturnus, the dyspeptic origin of, 400.
Nipples, supernumerary, occurrence of hairs in, 282.
Nitrogen, see *Blood Nitrogen*.
Nobel prize awards, 779.
Nodal rhythm, with reverse block and paroxysmal tachcardia, 286.
Noise, unnecessary, 570.
Nonagenarian, death by accident of a French medical, 840.
Nonsyphilitic diseases, the use of arsphenamine in, 489.
Nasomaniacs, neurasthenics and, 661.
Novak, Emil: the interpretation and clinical significance of uterine hemorrhages, 43.
Novarsenobenzol, cerebral reactions following injections of, 156; notes on the treatment of recurrent malaria by, 660.
Nurses, scarcity of, 614, 994; school for, in Bohemia, 62.
Nurslings, syphilis in, 910.
Nutrition, role of vitamines in, 359.
Nutritional disorders, the circulatory system in, 419.

Obstetrics and the state, 104; gynecology and, recent progress in, 275; the value of the Wassermann reaction in, based upon the study of 4,547 consecutive observations, 76, 829.
Obstruction, acute intestinal: a study of a second series of cases from the Massachusetts General Hospital, 489; intestinal, the cause of the continued high mortality in, 416; of the superior mesenteric vessels from bands, with threatened gangrene of the greater part of the small intestine, recovery, 749.
Occupation of the active and arrested cases in tuberculosis, 498.
Occupational therapy for the tuberculous, 572.
Oceanography, 576.
Ocular contusions, manner of production of, 315; mechanism, gastro-intestinal disturbances in affections of the, 196; symptoms of exophthalmic goiter, 617; symptoms of tetanus, 872.
Oettinger, Bernard: paralysis agitans and syphilis, 15.
Oil, intravenous use of drugs in, 118.
Olives, ripe, 19.
Omentum, cancer of the, 103.
Omphaloncus, non-malignant, 737.
Operation, late results of, 745.
Ophthalmia, phlyctenular, and its relation to tuberculosis, 329.
Ophthalmic conditions, some, blood analyses in, 250.
Ophthalmological congress, Oxford, 406.
Opium, alcohol and, the mental effects of, 577.
Opotherapy in pediatriac practice, 450; thyroid, 1064.
Optometry, Massachusetts statute requiring license to practise, held valid, 1063.
Orbit, osteomata of the, the etiology and pathogenesis of, 230; the pathogenesis of traumatic lesion of the, during delivery, 651.
Orchitis in mumps, 699, 743.
Orchitis, traumatic, changes of the testicle in, 775.
Organ therapy in thyroid and allied disorders, 631.
Organotherapy in Froelich's syndrome, 655.
Oriental boil, first case of contagion of, in France, 158.
O'Reilly, John J. A.: some history, a threat and its fulfilment, 1022; state medicine and the poetic doctor, 639.
Oscillometry in Asthenics and maniacs, 492.
Osteomata of the orbit, the etiology and pathogenesis of the, 230.
Osteomylitis, acute: experimental and clinical study, 83; for the frontal bone, suppurating frontal sinusitis and, extradural and subdural abscess following, 587.
Osteopaths not entitled to register birth and death certificates under Maryland statute, 187.
Osteosarcoma of the upper jaw in children, the etiology of, 863.
Ostitis cystica fibrosa of the ulna, 916.
Ouabaine, disappearance of ascites as a consequence of intraperitoneal injections of, 535.
Ouija board, the psychology of the, 547.
Outlet pelvimetry, 723.
Outlines, renal, the diagnostic value of the, 660.
Ovarion function on the medical and surgical methods adopted to secure the benefits of the ovarian secretions, an address on, 954; function following hysterectomy, 366.
Ovaries, animal, results of the exposure of, to the rays of radium, 29.
Ovary, the, as a cause of pain, 798; dermoid cysts of the; etiology, diagnosis, and treatment, 747; fibroma of the, 751; role of the, 282.
Overcooking vegetables, the influence of, in causing scurvy among children, 829.
Oxford ophthalmological congress, 406.
Oxygen, the therapeutic use of, 198.

P

Pain, abdominal, in diseases of the kidney and ureter, 870; abdominal, spondylitis and, with a discussion of nerve-root symptoms simulating visceral disease, 28; chronic abdominal, 573; the ovary as a cause of, 798.
Pains, labor, dogwood for, 630.
Palestine, first medical journal in, 275.
Palikinesis, palilalia and, 864.
Palilalia and palikinesis, 864.
Pancreas, report of a case of primary carcinoma of, surgical jaundice, 767.
Pancreatic disease, the blood and urine in, 533; infantilism, 661.
Papillomata of the larynx in children, 357.
Paralysis agitans and syphilis, 15; facial, and Weber's syndrome, 652; general, the precipitin test for globulin in the arachnoid fluid in, 913; infantile, the early orthopedic treatment of, 995; of the left recurrent nerve in mitral stenosis, the pathogenesis of, 272; of the respiratory muscles, a case of, 370.
Paraoxyphenylethylamine, action of, 278.
Paraffinomas from injection of camphorated oil, 158.
Parasites, intestinal, as a cause of appendicitis; report of a case, 143; intestinal, infrequency of, in young children, 71; of Venezuela rats, 168.
Paratyphus B., "cream cakes" and, 871.
Pardee, Irving H.: epidemic encephalitis, 804.
Parents, minor patient's, warning, of infectious disease, 20.
Park, Dr. Edward A., called to Yale Medical School, 1067.
Parkinson's disease, arsenic in, 822.
Parsley, infusion of, in the treatment of gall-stones, 588.
Patella, fractured, treatment of; diathermy, 923.
Pathogenesis of traumatic lesion of the orbit during delivery, 651.
Pathology, anatomy, physiology, and, of the tonsillar structures in relation to cryptogenic infections, 593.
Patients, delirious, question of hospital's care in safeguarding, 398.
Pause, voluntary apneic, 526.
Pavor nocturnus, nightmare and, the dyspneptic origin of, 400.
"Pedology," antiquity of the term, 574.
Pellagra and the "sore mouth" of dogs, 153; etiology of, 27.
Pelvic cavity, hemorrhages into, other than those of ectopic pregnancy, 77.
Pelvimetry, outlet, 723.
Penis, gangrene of, in old men, 503; gangrene of the sulcus of, due to the bacillus perfringens and septic vibrio, 737.
Perfume, the, of the human body, 672.
Periodicity theory, the Fleiss, 30.
Peritonitis, ascending, of the puerperal type, surgical intervention in, 790.
Pernio, see also *Chilblain;* senile, 735.
Pertussis, intramuscular injections of ether in, 703; see also *Whooping cough.*
Pessary, Gehrung, 749.
Pestilences of Eastern Europe, progress of the warfare against, 1030.
Pharmaco-endocrinology, the abandonment of therapeutics in medical schools due to neglect of its curative subdivision, 463.
Pharmacy, military medicine and, international congress of, 1035.
Phenol, alcohol versus—the value of the "no good," 956.
Pheochromocytoma of the suprarenal gland with hypertrophy of the left myocardium, case of, 450.
Phimosis and the guillotine, a new instrument for circumcision, 1061.
Phlebectasis, subcutaneous, of the lower thoracic and upper abdominal regions, 28.
Phlegmon, gas, is Ludwig's angina a, 946.
Phlyctenular ophthalmia and its relation to tuberculosis, 329.
Phototherapy in benign diseases of the skin, 874; report on, 922.
Phosgene, rapidly fatal poisoning by, 694.
Physical measures, the futility and unfairness of improper technique in the use of all, 875.
Physician, a study of acute infections of the ear as seen by the, 415; defendant, statement that, protected by insurance held prejudicial, 270; family cooperation of the specialist and the, 412; ratification by corporation of its agent's unauthorized employment of, 650; the future, 1075; the future of the, 323.
Physicians, Armenian, martyrdom of, during the European war, 190; classification for taxation of, according to length of practice is discriminatory and invalid, 480; cooperation among, 999; the two classes of, 154.
Physician's account, compromise and settlement of, 270; action against husband for medical services to wife, 270; declarations, hearsay evidence of, inadmissible, 268; fees under contract, industrial board has no jurisdiction to determine, 774 services, implied promise to pay reasonable value for, 187; testimony, objection to, as privileged must be timely, 270; testimony, patient's privilege as to, 314.
Physiology, anatomy, and pathology of the tonsillar structures in relation to cryptogenic infections, 593; Cartesian, value of, 597; clinical, 836; physical exercise and, 655; relation of, to medicine, 578.
Physiotherapy in the treatment of industrial disabilities, 876; in the United States Navy, 877; the relation of, to surgery, 877.
Physiotherapeutic measures, standardization of, 835.
Picric acid, the preparation of the skin for operation, with special reference to the use of, 752; use of, its preparation of the skin, 82.
Pierce George H.: outlet pelvimetry, 723.
Pilocarpine and adrenalin, bronchial asthma: response to, 668.
Pitfield, Robert L.: Biddy and the coal bin. A case of polyglandular disease, 351.
Pituitary extract, the induction of labor: indications and methods with special reference to the use of, 75.
Placental gland and placental extract, 912.
Plague, bubonic, fixation abscess in the treatment of, 317; cattle, 615, 1036; cattle, the epidemic of, 783; epidemic at Avignon in 1721, further data concerning the, 756; human, the diagnosis of, 323.
Plant, sacred, what was the, of the ancient Mexicans, 1081.
Pleural disease in infants and children. With special reference to empyema, 238.
Pleurisy, the surgical aspects of, 1057.

Pluriglandular insufficiency, case of, 746.
Pneumococci, types of, in the throats of one hundred normal persons, 870; virulence of the, 149.
Pneumonia, acident and, causal relation between, not known, 691; a study of, during the recent epidemics, 329; aspiration, heart displacement apparently due to mediastinal emphysema following, 371; influenza, complicated by empyema in an infant, 62; influenzal, 566; nontuberculous lung changes following, 1037; patients, and how they may be saved, 745; segregation of, 326; the segregation of, 660; with diarrhea, 440.
Pneumothorax, artificial, 444; artificial, gunshot wound in case of, 500; artificial, report on, 1040; artificial, the *x*-ray as an essential guide for producing, in advanced pulmonary tuberculosis, 828; international association of "pneumothorax artificialis," 444.
Poisoning by phosgene, rapidly fatal, 694.
Poliencephalitis of influenza, lethargic encephalitis and the, 30.
Polioencephalomyelitis, epidemic, acute, focally disseminate, nonpurulent (lymphocytic), toxic-infections, 566.
Poliomyelitis, anterior (infantile paralysis), the place of muscle re-education in the, 785; epidemic, serum treatment of, 948.
Polyarthritis, acute, treatment of, 96.
Poyiglandular disease: Biddy and the coal bin, a case of, 351.
Polyneuritis in France during the war, 840.
Porter, William H.: chemically pure anhydrous dextrose as a therapeutic agent, 973; the therapeutics of decreasing body alkalinity, 471.
Potassium nitrate in cancer, 569, 991.
Pottenger, F. M.: the individual factor in disease, 647.
Pouches, gastric, in biloculation of the stomach, 526.
Powers, Charles A.: All German, Austrian, and Turkish surgeons expelled from the International Surgical Society, 443.
Practice, contract, in Old Spain, 714 of medicine without a license not a joint offense, 861.
Practising without license, 314; without a license, defective information for 563; without license—indictment under New York act must name individual treated, 147; without license, suit for penalty for, is civil in New Jersey, 944.
Practitioner, the nights of a Bordeaux, 1081.
Precipitin test for globulin in the arachnoid fluid in general paralysis, 913.
Precipitins for egg albumin in stools, 373.
Preclinical branches, the present status of, 999.
Pregnancy, accidental hemorrhage; and latent syphilis, 1038; cesarean section, hematuria in, 748; and the puerperium, suppression of urine in, 323; ectopic, the diagnosis and treatment of, 997; nausea and vomiting in, 252; pyelitis in, with report of cases, 750; right tubal—fourth month with rupture into the cecum, 957; splenic leucemia associated with, 750; tubal, full-time. Cesarean salpingectomy; recovery, 29; uterine fibroids complicating, 490.
Prenatal care and maternal welfare work in Paris under the children's bureau of the American Red Cross, 78; the significance of syphilis in, and in the causation of fetal death, 240.
Prescription writing, the ethics of, 316.
Prianism, a case of, resulting from rapidly spreading malignant myxosarcoma with generalized metastases, 372; idiopathic or neurogenic, 73.
Prize, Alvarenga, 780; Nobel, awards, 779.
Problems, racial, some, social evils, and modern crusades, 239.
Proprietary compounds containing poisons, labeling of, 20.
Prostate, etiology of senile hypertrophy of, 906.
Prostatectomy, 155, 195.
Prostatic backache, 144.
Protein shock reaction in leprosy, 607.
Pruritus ani and vulvæ, the operative cure of, 702.
Pseudocholecystitis, 749.
Pseudo-pregnancy in a subject with major hysteria, 232.
Psoriasis, dissolved sulphur in the treatment of, 671; etiology of, 535; universal, *x*-ray treatment of, 355.
Psychic inhibition of menstruation, 274.
Psycholepsy, 738.
Psychology, descriptive, and medicine, 338, 404; in relation to the industries, 579; the, of the cardiac and the doctor, 918.
Psychoneuroses, the physical element in the, 281.
Psychopathic degeneration and disequilibrium, 318.
Psychoses, acute, in diseases of the heart, 249; dreams and, parallel between, 341; relations of neurasthenia to the, 274.
Pudendal hernia, operated by the abdominal route, 957.
Puerperal lesions, pathology of common, 752; metritis, chronic forms of, 947; sepsis and its treatment, 616.
Puerperium, pregnancy and the, suppression of urine in, 323; some cases of thrombophlebitis during the, following influenza, 751.
Pulsation, transmitted, dermoid cyst of the mediastinum with, 1019.
Pulse rate, a study of the correlation of the basal metabolism and the, in patients with exophthalmic goiter, 165.
Purpura hemorrhagica, streptococcic angina with, and multiple infarcts of the skin and subcutaneous tissue in a child two years old, healing under Dakin's solution, 371.
Pyelitis et ureteritis et cystitis cystica, 197; in infancy and childhood, the treatment of, 913; in pregnancy, with report of cases, 750.
Pylorospasm, roentgen-ray findings with the delineator in cases of, 884.
Pylorus, congenital hypertrophic stenosis of the, surgery of, 197.
Pyorrhea alveolaris, infected apices of teeth and, 52, 237.

Q

Quadruplets, survival of, 241.
Quarantine regulations, 187; stations, Swiss, 910.
Quinine and its related alkaloids in pharmacology and therapeutics, 363; by mouth, 713; diagnostic methods in exophthalmic goiter, with special reference to, 887; in fibrillation and tachysystolia, 703; in the treatment of hemoptysis, 313.

R

Rabelais in libraries, 269.
Rabelais' remark on the throat, 561.
Rabies disappears from Poland, 84; is lethargic encephalis a form of?, 608.
Racial problems, some, social evils, and modern crusades, 239.
Radiation, factors influencing the quantitative effects of, 581; of the hypophysis for bronchial asthma, 661; results of treatment of malignant disease of the upper air tract by, 581; the treatment of certain gynecological diseases with, 979.
Radioactivity, the influence of, in the treatment of hypertension, 1051.
Radiography, superfetation diagnosticated by, 871.
Radiology, work of the institute of, at Monte-Video, 924.
Radioscopy and radiography of the spleen, 736.
Radiotherapy, radicular, 564.
Radium and roentgen rays, experiments on the therapeutic action of, 286; hospital in Manchester, 953; in uterine hemorrhage, 684; needles, the rôle of, in the treatment of malignant disease, 874; operation or, for operable cancer of the cervix, 79 results of the exposure of animal ovaries to the rays of, 29; some immediate effects following the use of, for non-malignant uterine bleeding, 453; symposium on, dosage, envelopes and duration of treatment, 581; the therapeutic value of, 359; therapy in uterine cancer, 121; therapy, technique of, in cancer of the uterus, 785; treatment of cervical cancer, an analysis of the failure in, 79.
Radius, subluxation of the head of the, based on the study of thirty-seven cases, 981.
Randall, G. M.: botulism: a report of fifteen cases, in three series, 763.
Rasmussen's aneurysm, 822.
Ratchford, B. K.: malnutrition from underfeeding in a two and one-half year old child, 181.
Rats, parasites of Venezuela, 168.
Rays, actinic, 922.
Reaction, the complement fixation, in tuberculosis, 660; the leucocytic, in a paratyphoid dysentery and following vaccine inoculations, 1036; the Wildholz, 158.
Rebreathing and ergometer determinations as a method of estimating cardiac efficiency, 249.
Reconstruction work in the United States Army, the use of the static machine in, 876.
Recruits, a collective investigation of ten thousand, with doubtful heart conditions, 29.
Rectum, cancer of the, diagnosis of, 312; cancer of the, advances in surgical treatment of, 1073.
Reder, Francis: hemangioma and lymphangioma, their response to the injection of boiling water, 519.
Redfield, Casper L.: the germplasm, 396.
Remer, John, and Witherbee, W. D.: the cause of *x*-ray burns, 183; and Witherbee, W. D.: *x*-ray treatment of universal psoriasis, 355.
Renal calculus with negative *x*-ray findings, 195; outlines, the diagnostic value of, 660.
Repression, psychological, a note on our present conception of, 996.
Research, electrotherapeutic, 835.
Respiratory diseases, acute, report of the prophylactic vaccination of 1536 persons against, 1919-1920, 1004; diseases, prevention of, 799; function, disorders of, in cardiac disease, 669; infections, acute, the bacteriology of the, not including the pneumonias, 1003 — infections and respiratory contacts, a bacteriological study of, as encountered in the American Expeditionary Forces, France, 94.
Rest, postural, for pulmonary tuberculosis, 497.
Resuscitation in death under anesthesia, 997.
Rheumatic fever, acute, salicylates in, 22.
Rhinophyma, 665.
Rhythm, nodal, with reverse block and paroxysmal tachycardia, 286.
Rhythmic currents, 834.
Richardson, Frank Howard: the evolution of a children's clinic, 127.
Rickets is, a deficiency disease?, 746; some observations on, 369.
Right to practise a valuable property right—powers of board of medical examiners to suspend licenses, 691.
"Ringers," physiological and pathological, 619.
Robinson, Edward Percy: electrochemism in the etiology and therapeusis of cancer, 133; potassium nitrate in cancer, 569, 991.
Robinson, Beverley: deception and self-deception, in the practice of medicine, 67; drugs and their active principles in relation to the treatment of disease, 983; infected apices of teeth and pyorrhea alveolaris, 237.
Rockefeller Foundation, offer of, to University College Hospital Medical School, 110; to assist medical schools in Central Europe, 1067.
Roentgen ray, actinomycosis treated with methylene blue and, 996; as a hemostatic, 271; dose estimation of, 1072; findings in appendical obliteration, 1072; findings with the delineator in cases of pylorospasm, 884; radium and, experiments on the therapeutic action of, 286; standardized, in the treatment of skin diseases, 995; therapy of malignant growths of the uterus, 785.
Roentgen rays, radium and, experiments on the therapeutic action of, 286; therapy of malignant growths of the uterus, 785.
Rogers, John: organ therapy in thyroid and allied disorders, 631.
Rosewater, Charles A.: what is an intoxicating beverage, 976.
Rubber glove, where the, is behind the times, 747.
Rummo-Ferranini genitodystrophic geroderma (senilism), lean type, due to tardy hereditary syphilis, 1009.
Sade, the Marquis of, side lights on, 948.
Saint Anthony's fire, 402, 611.

Sajous, Charles E. de M.: medical men in the Hall of Fame, 67; the abandonment of therapeutics in medical schools due to neglect of its curative subdivision: pharmacoendocrinology, 463.
Salicylates in acute rheumatic fever, 22.
Salfingectomy, cesarean: recovery, full-time tubal pregnancy, 29.
Salzman, S. R.: Tonsil infections, 85.
Sanatoria for cardiacs, 33.
Sanatorium treatment of cardiac cases, 34.
Sanitary inspectors' association, conference of the, 697.
Saratoga-Nauheim baths, natural, at Saratoga Springs, N. Y., a study the, 262.
Sarcoma, bone, conservative treatment of, 610; of the kidney, 370; primary, of the thymus, 370; syphilis, Vincent's angina and, of the pharynx, one condition following the other in the order named, report of a case of, 581.
Sarcomatous tranformations of uterine fibroids, 46.
Satterthwaite, Thomas E.: endocrinology and the heart, 510.
Saunders, M. B.: pellagra and the "sore mouth" of dogs, 153.
Scalp, esthetic grafting of, 29.
Scar, cesarean section, rupture of in subsequent pregnancy and labor, 701.
Scarlet fever, a biological study of hemolytic streptococci from throats of patients suffering from, 240.
Schedule, a twenty-four hour, for boys, 418.
Schoppegrell, William: allergy, anaphylaxis, and immunity in hay fever and asthma, 216.
Schulman, M.: parenteral protein treatment of arthritis, with special reference to milk injections; the relation to anaphylaxis, 47.
Scholz, Thomas, Einhorn, Max, and: roentgen-ray findings with the delineator in cases of pylorospasm, 884.
Sciatica from an orthopedic standpoint, 157; new signs of, 730.
Science, preliminary, the place of, in the medical curriculums, 239; the unity of, and the unity of matter, 777.
Sclerosis, multiple, of commotional origin, 282; of the facial glands, 692.
Scoliosis, functional, the causes and occurrence of, in college men, 954; the treatment of, 838.
Scurvy, the influence of overcooking vegetables in causing, among children, 829.
Seasickness, nature and treatment of, 783.
Senectute, de, 357, 444.
Sepsis, chronic, hemorrhagic, case of, 241; hidden, 1073; puerperal, 534; puerperal, and its treatment, 616; the treatment of abortion complicated by, 752; tonsillar, 241.
Septicemia, bacillus aerogenes, with methemoglobmemia, following abortion, 452; pneumococcus, the formation and fate of methemoglobin in, 334.
Serositis, multiple, 616.
Serum, a vaccine and, for yellow fever, 1031; horse, anthrax cured with, 612; salvarsanized, intracistern injections of, in neurosyphilis, 783; specific, chancroidal infection of a year's duration cured by a, 240; treatment, a summary of the results of the, of 267 cases of cerebrospinal fever, 701; treatment of epidemic poliomyelitis, 948.
Servoss, George L.: fighting fire with fire, 941.
Settlement house, American, in Paris slums, 1008.
Sex conflict in adolescence, 204; diagnosis of through measurements of the atlas, 401.
Sexual functions, relations of the cerebrum to the, 106.
Sharpe, N. C., Anderson, H. B., Mann, R. W., and: chronic tonsillar infections, 590.
Sheehan, Joseph Eastman: a case of leontiasis ossea, 1017.
Shell shock inquiry, 572.
Shock, protein, reaction in leprosy, 607.
Shoulder and hip, certain fundamentals in the treatment of, 917; recurrent dislocation of the, operative results, 80.
Shufeldt, R. W.: mammology—an anatomical and taxonomic consideration of the group to which man belongs, 421, 674.
Sigmoid impaction — its significance, pathology, and treatment, 837.
Sign of the tongue, the, in verminosis, 924; spinal, in gastric crises of tabes; the point of origin of such attacks, and their treatment, 728; the duct, in mumps, 372.
Signs, pulmonary physical, studies in vibrations causing, 502.
Simulation and alcoholism, 872.
Sinus anomalous, sigmoid, thrombosis, with report of a case, 388; lateral, thrombosis, an unusual case of, 942; maxillary, operative treatment of malignant neoplasms of the, 188; suppuration, frontal, meningitis due to, with a report of three fatal cases, 587.
Sinuses, sacrococcygeal infundibula and congenital paracoccygeal, 105; nasal, some indications for operation on the, in children, 585.
Sinusitis, frontal, and osteomyelitis of the frontal bone, extradural and subdural abscess following, 587; maxillary, a new and hitherto undescribed form of, 586.
Skill, degree of, not limited to locality in Missouri courts, 691.
Skin, benign diseases of, phototherapy in, 874; diseases, standardized roentgen ray in the treatment of, 995; grafting, 686; the preparation of the, for operation, with special reference to the use of picric acid, 752; the use of picric acid in the preparation of the, 82; venipuncture in the treatment of certain diseases of, 660.
Skull, fractured, finding as to, held not sustained, 734.
Sleeping sickness, influenza and, 17; laboratory transmission of, 322.
Smallpox, how, was fought in Milan, 84.
Smith, Joseph: Monakow's views on cerebral localization, 931.
Soaps in relation to their use for hand washing, 281.
Social evils, some racial problems, and modern crusades, 239; maladjustment as seen in the children's clinic in the department of psychopathology at Cornell University, 205; treatment, 203.

Society Reports:

"Sore mouth" of dogs, pellagra and, 153.
Spanish health statistics, some, 55.
Specialist, cooperation of the, and the family physician, 412.
Speech, defects of hearing and, demonstration of reconstruction section of, 36.
Spencer, Hugh R.: a bacteriological study of respiratory infections and respiratory contacts as encountered in the American Expeditionary Forces, France, 94.
Spinal cord, a lecture on the early symptoms and diagnosis of diseases of the, 197; cord tumors, symptomatology of, 784; punctate, injections of, treatment of typhus by, 830; puncture headache, new procedure for the prevention of, 598; reflex system, the diagnosis of chronic conditions by, 783.
Spine, anomalies of the, 22; the, as an entity; its outgoing nerves; its bony canal, 838.
Spleen, radioscopy and radiography of the, 736.
Splenectomy, blood findings five years after, 371; report on three cases of splenic anemia treated by, 1041.
Spondylitis and abdominal pain, with a discussion of nerve-root symptoms simulating visceral disease, 28.
Sputum, tuberculous, the bacterial flora of 1060.
Squill, clinical observations on the digitalis-like action of, 700.
Stammering as it is, 935; the nature and cause of, 616.
Stasis, intestinal, a brief experience with appendicostomy and cecostomy for, in epilepsy and neurasthenia, 449.
State Board Questions and Answers, Connecticut, 39, 122, 206; Florida, 290, 375, 459; Oregon, 1046; Texas, 542, 625, 708; West Virginia, 794, 878, 961.
State Medicine and the poetic doctor, 639.
Static machine, the use of, in reconstruction work in the United States Army, 876.
Statistics, some vital, 609.
Status thymicus, the psychic factor in anesthesia—death in, 65.
Statute of limitations governing time of action, 607.
Steinach, William: nervous and mental mechanisms: the nerve impulse, 17.
Stenosis and insufficiency, tricuspid, 953; hypertrophic; failure of gruel feeding; operation; slight improvement, 370.
Stercobiline, practical significance of, 492.
Sterility in the female; a report of operative cures, 77; of masculine origin, 318.
Stevens, J. Thompson: the management of malignancy by the combined methods, 815; the treatment of certain gynecological diseases with radiation, 979.
Stewart, Douglas H.: dilatation and plication of the caput coli, 383; paracoccygeal fistula, 528.
Stigmata, dental, in the diagnosis of obscure congenital lues, 830.
Stimulation, irritability and, 288.
Stomach, cancer of the, repugnance to meat in, 525; descensus of the, the diagnosis and a new treatment of, 73; penetrating ulcer of the posterior wall of the, 664; resection for carcinoma of, (four years ago), 664; should cancer of the, be subjected to operation, 746; the gastric pouches in biloculation of the, 526.
Stomatitis, is ordinary aphthous, a form of foot and mouth disease, 746.
Stone, Chester T.: phimosis and the guillotine, a new instrument for circumcision, 1061; the guillotine, a simple one-man instrument for doing circumcisions, 479.
Stools, on the significance of blood and soluble "albumin" in, 448.
Streptococcus mucosus, a brief case report of an epidemic of hemorrhagic diarrhea due to the, 329.
Stricture, relation of deep, of large caliber to disease of lower urinary tract, 29.
Strictures, multiple, of the esophagus, a case of, cured after repeated dilatation with graduated bougies, 581.
Strikes and health, 909.
Strobel, Joseph E.: quinine in the treatment of hemoptysis, 313; the bacterial flora of tuberculous sputum, 1060.
Strophanthin and digitalis, on certain differences in the action of, in patients, 333.
Study, J. N.: cancer of the omentum, 103.
Sturtevant, Mills: the treatment of gastric achylia, 939.
"Subconsciousness" and dreams, 505.
Suboxidation syndrome in childhood, 457.
Subscriptions, compulsory, the question of, 192.
Sugar, blood estimation, sources of error in, 776; see also *Blood Sugar:* dressing in surgery, 148; in the blood, 870.
Suicides of women and children increase, 275.
Sulphur dioxide, immunity to tuberculosis among workers in, 310; dissolved in the treatment of psoriasis, 671.
Superfetation diagnosticated by radiography, 871.
Superimpregnation, 399,

Suprarenal glands, action of the *x*-rays on the, 231; case of pheochromocytoma of the, with hypertrophy of the left myocardium, 450; virilism, 956.
Suprarenins, synthetic, and their derivatives, 364.
Surgeons, all German, Austrian and Turkish, expelled from the International Surgical Society, 443.
Surgery, Congress of the International Society of, 406; face, 487; good and bad, an address on, 955; intestinal and rectal, some fundamental principles underlying, 432; kidney and ureteral, recent progress in, 645; minor, an evaluation of, 138; of the head, group study in the, 71; of the neck, 386; sugar dressing in, 148; the relation of physiotherapy to, 877; vaginal, certain procedures in, 748.
Suspension and dissection, intrinsic carcinoma of the larynx with a second report of cases operated on by, 584.
Sutures, presection, end-to-end anastomosis of the intestine by, 618.
Switzerland, public hygiene in, 1070.
Sympathicotonus, eserine in, 654.
Symptomatology, the recrudescence of, 775.
Syncope, chloroform, averted by direct heart massage, 150.
Syndrome, coprological, pancreatic dyspepsia and its, 865; effort, in children and young adults, 372; Froelich's, organotherapy in, 655; Hodgkin's, two cases of, in Bahia, 830; of Bloch, 401; thalamic, in cerebral arteriosclerosis, 449; the acidosis, 820; the Adams-Stokes, 923; the Dubreuil-Chambardel, 745; the suboxidation, in childhood, 457; Weber's, facial paralysis and, 652.
Syndromes, peduncular and bulbo-protuberantial, the pathogenesis of, in typhoid fever, 21; the grand dyspeptic, 745.
Syphilis, acquired, in the aged, 730; and lethargic encephalitis, 503; as a cause of delayed healing in non-infected abdominal incision, 700; congenital, a method of treating, 954; congenital, in infants and children, further progress in the study of the relative efficiency of the different mercurial preparations in the treatment of, as determined by a quantitative analysis of the mercury elimination in the urine, 330; frequency of, with cancer of the lips, tongue and buccal mucous membrane, 617; generalized, the production of, in the rabbit by local inoculation, 288; hereditary, a study of the incidence of, 331; hereditary, the new laws of, 73; in Africa, 504; in children of school age with heart disease, 919; in nurslings, 910; insontium, 157; is there a neurotropic, 190; of the nervous system in children, 1076; paralysis agitans and, 15; the significance of, in prenatal care and in the causation of fetal death, 240; pregnancy and latent, 1038; the treatment of, 477; tuberculosis and, a study of the progressive changes in the aorta and lung as shown by *x*-ray in, 499; Vincent's angina, and sarcoma of the pharynx, one condition following the other in the order named, report of a case of, 581; Wassermann-fast, a clinical study of, with reference to prognosis and treatment, 955.

T

Tabes, a spinal sign in gastric crises of; the point of origin of such attacks, and their treatment, 728; the early signs of, 447.
Tachycardia, paroxysmal, nodal rhythm, with reverse block and, 286; paroxysmal, of ventricular origin and its association with coronary thrombosis, 286.
Tachysystolia, fibrillation and quinine in, 703.
Taylor, J. Madison: common motor disorders, disuse cripplings, neuroses, post-infective and others, 554.
Technique, importance of, in the application of external therapeutic measures, 874; improper, the futility and unfairness of, in the use of all physical measures, 875.
Teeth, infected apices of, and pyorrhea alveolaris, 52, 237; the relation of, to general medicine, 217.
Temperance breakfast, annual, 246.
Temperature, cutaneous, relations between the temperature of the expired air and the, 661.
Temperatures, superficial and deep, effects of hot and cold applications on the, 744.
Tendon of flexor longus hallucis, recovery of a needle from, 728.
Teratomata, intrathoracic, 286.
Terry, C. E.: inconclusive experiments concerning drug addiction, 1033.
Tertian fever, benign, researches on the treatment of, 114.
Test, blood sugar tolerance, as an aid in the diagnosis of gastrointestinal cancer, 285; complement-fixation, a study of the preparation of antigens from cultures of the tubercle bacillus for the, 288; indol, on the spinal fluid for rapid diagnosis of influenzal meningitis, 996; intradermal protein sensitization, report of a case of anaphylaxis following, 371; knee-jerk, a method for standardizing the, and its measurement, 982; luetin, status of the, 522; precipitin, for globulin in the arachnoid fluid in general paralysis, 913.
Test-meal, fractional, an investigation of gastric function by means of the, 617.
Testamentary capacity, 147.
Testicle, changes of the, in traumatic orchitis, 775; ectopic, volvulus of an, 738.
Testimony as to physical condition of patient excluded, 187.
Tetanus, ocular symptoms of, 872.
Tetterwort, see *Chelidonium*.
Thalamic syndrome, in cerebral arteriosclerosis, 449.
Therapeutic hints, 168, 252, 294, 378, 588, 630, 671, 713, 756, 1050; information wanted, 25; measures, external, importance of technique in the application of, 874.
Therapeutics, Arsonval on the history of high frequency currents in, 1081; modern, 565; the abandonment of, in medical schools due to neglect of its curative subdivision: pharmacoendocrinology, 463.
Thermometer, the use of, in mental disease, 869.
Thom, Burton Peter: acquired syphilis in the aged, 730.
Thoracoplasty, extrapleural, in the treatment of pulmonary tuberculosis, 870.
Thorax, cholesterol, 953; *x*-rays in the diagnosis of tumors of the, 660.
Thornwaldt's disease, 1038.
Throat, Rabelais' remark on the, 561; the, in botulism, 442.
Thrombophlebitis, during the puerperium following influenza, some cases of, 751.
Thrombosis, anomalous sigmoid sinus, with report of a case, 388; coronary, paroxysmal tachycardia of ventricular origin and its association with, 286; lateral sinus, an unusual case of, 942; portal, a case of, 370.
Thymus death, 409; gland, the physiology of the, 149; primary sarcoma of the, 370.
Thyroglossal cysts, the complete extirpation of, 525.
Thyroid and allied disorders, organotherapy in, 631; feeding, hypothyroidism twenty-six years' supplemental, 1054; gland, woman's intuition and the, 909; the toxic: its treatment by ether-oil colonic anesthesia, 749; therapy, 1064.
Tibbets, F. S., and Gwathmey, James T.: a preliminary report on laboratory experiments to determine the value of certain agents in connection with surgical operations, 1021.
Tinea tonsurans, 713.
Tissue resistance to cancer, some factors that determine, 752.
Titus, Edward C., and de Kraft, Frederic: employment of diathermy and galvanism in the management of sequelæ of occlusion, partial or complete, and of rupture of the cerebral arteries, 851.
To him that hath, 22.
Tolerance test, glucose, in chronic vascular hypertension, 164.
Tomkins, Ernest: stammering as it is, 935.
Tongue, lips, and buccal mucous membrane, frequency of syphilis with cancer of the, 617; the sign of, in verminosis, 924.
Tonsil infections, 85.
Tonsillar infections, chronic, 590; structures, the anatomy, physiology, and pathology of the, in relation to cryptogenic infections, 593.
Tonsillectomy, the place of, in the management of cardiac disease in children, 919.
Tonsillitis, acute follicular, 168.
Toxin-antitoxin, results of the use of, in immunization against diphtheria during a period of six years, 1006.
Toxic idiopathies, an address on, 408.
Toxemia, intestinal, benign mammary tumors and, 751.
Toxemias, various, the injurious effects on the eye of the, 538.
Trachea, larynx, and, treatment of post-diphtheritic stenosis of the, 282.
Trachoma, treatment of, by arsenobenzol, 1036.
Transfusion, blood, 534; blood, early history of, 755.
Treub, death of, 840.
Tricuspid stenosis and tricuspid insufficiency, 953.
Trigeminal neuralgia, the role of deep alcohol injections in the treatment of; neuralgias, the major, and their surgical treatment based on experiences with 332 Gasserian operations, 448.
Truancy, schol children who through lack of emotional control develop habits of, 205.
Tuberculosis, abdominal visceral, pathology of, 661; and hyperthyroidism, differential diagnosis of, 914; and influenza, 498; and syphilis, a study of the progressive changes in the aorta and lung as shown by *x*-ray in, 499; certain symptomatological aspects of pulmonary cavities in, 989; codliver oil in, 778; dementia precox and, 450; food values in, some remarks on, 914; immunity to, among workers in sulphur dioxide, 310; is, contagious? 943; nasal, an unusual type of, 583; occupation of the active and arrested cases in, 498; odds and ends in, 499; of the genitourinary tract, diagnosis and treatment of, 280; of the larynx, the treatment of, 503; phlyctenular ophthalmia and its relation to, 329; pulmonary, a study of destruction and repair in, 500; pulmonary, a study of the effect of, on vital capacity, 870; pulmonary, a study of the metabolism and heat regulation in, 669; pulmonary, and conditions simulating the same, 412; pulmonary, contributions to the treatment of, 176; pulmonary, destruction and repair in, 828; pulmonary, extrapleural thoracoplasty in the treatment of, 870; pulmonary, kidney in, 862; pulmonary, postural rest for, 497; pulmonary, the classification of, 408; pulmonary, the complement-fixation test in; its use as a means of diagnosis, 744; pulmonary, the use of the intravenous injection of calcium chloride in the treatment of, 503; pulmonary, the vital capacity constants applied to the study of, 72; pulmonary, the *x*-ray as an essential guide for producing artificial pneumothorax in advanced cases of, 828; schemes, how, fail, and why, 968; the complement fixation reaction in, 660; the crusade against, 903; the hereditary factors in the resistance of, 287.
Tuberculous, occupational therapy for the, 572.
Tumors, benign mammary, and intestinal toxemia, 751; of the bladder (pathology), 998; of the hypophysis, the *x*-ray treatment of, 986; of the thorax, *x*-rays in the diagnosis of, 660; spinal cord, symptomatology of, 784.
Tweddell, F.: immunity to tuberculosis among workers in sulphur dioxide, 310.
Typhoid fever, the diagnosis and prognosis of the infectious erythemata of, 653; intussusception in, 481; the pathogenesis of peduncular and bulbo-protuberantial syndromes in, 21; the menace of, in Europe, 910.
Typhus, benign, in France, 198; fever, 904; menace of, in Eastern Europe, 322; to fight, 698; treatment of, by injections of spinal punctate, 830.

U

Ulcer, chronic gastric, the surgical treatment of, 441; duodenal, fluoroscopic diagnosis of, 666; duodenal, its early diagnosis and treatment, 348; duodenal, the site and number of, 524; gastric and duodenal, 532; gastric and duodenal, a critical review of five hundred cases of, 1037; gastric and duodenal, and their surgical

treatment, 836 gastric and duodenal, the diagnosis of, 836; gastric and duodenal, the results of operation in, 196; gastric, and its treatment, 832; gastric, surgical treatment of, 244, 336; gastric, the dietetic treatment of, based on experimental studies, 289; gastrojejunal (two cases), 664; lingual, the differential diagnosis of, 63; of the cornea, 168; penetrating, of the posterior wall of the stomach, 664; peptic, surgical treatment of, 998; pyloric, a case of, with symptoms that might be ascribed to an existing epigastric hernia, 664; the results of operation on gastric and duodenal, 665.
Ulna, ostitis cystica fibrosa of the, 916.
Ultra violet light as a medical adjuvant, 922.
Unconscious, the, 160, 599.
Unity of science, the, and the unity of matter, 777.
Uranium salts, action of, on neoplasms, 484.
Urea, the excretion of, 333.
Ureter, kidney and, abdominal pain in diseases of the, 870; the treatment of calculi impacted in the pelvic portion of, 408.
Ureteral, kidney and, surgery, recent progress in, 645.
Ureters, female pelvic, 749.
Urine, lead in the, in neurocirculatory disturbances, 869; nature of the reducing substance in the, of children suffering from nutritional disorders, 328; suppression of, in pregnancy and the puerperium, 323; the blood and, in pancreatic disease, 533.
Urotropin, sweetened, treatment of icterus by, 450.
Uterine fibroids, sarcomatous transformation of, 46; hemorrhage, the interpretation and clinical significance of, 43.
Uterus, a new method of covering raw surfaces upon the, 79; cancer of the, in young women, 792; cancer of the, landmarks in the treatment of, 672; cancer of the, technique of radium therapy in, 785; prophylaxis and treatment of rupture of the, during labor, 905; röntgen therapy of malignant growths of the, 785.

V

Vaccination, prophylactic, report of the, of 1,536 persons against acute respiratory disease, 1919-1920, 1004.
Vaccine, a, and serum for yellow fever, 1031; and gland therapy as an aid in our practice during the past twenty months, 923; detoxicated Kiebs-Loeffler, treatment of diphtheria carriers with, 1038; detoxicated, some observations on the treatment of gonorrhea with, 489; influenza, the value of immunizing doses of, in the prophylaxis and specific treatment of influenza, 100; inoculations, the leucocytic reaction in a paratyphoid dysentery and following, 1036; streptococcus, erythema nodosum: its treatment by, 859.
Vaccines for whooping cough, 950; fresh, the use of, in whooping cough, 762; in general practice, 813; in the treatment of chilblains, 610; use of fresh, in whooping cough, 369.
Vagina, case of congenital absence of, with other abnormalities, 748.
Vaginal surgery, certain procedures in, 748.
Van Beneden, a statue of, 615.
Van Court, F. F.: the elimination of fear, 951.
Van Paing, John F.: the surgical aspects of pleurisy, 1057.
Vance, J. G., Nice, Charles M., and: etiological classification of heart disease, 605.
Variola, the early diagnosis of, 72.
Vasomotor disturbances, unusual, 1000.
Vascular hypertension, the ultimate prognosis in, 501.
Vegetable drug deletions, proposed, 265.
Vegetations, adenoid, in the adult, 703.
Venipuncture in the treatment of certain dieases of the skin, 660.
Venereal disease, control of, in Denmark, 531; disease control, notes on, 559; disease control, the problem of, 413; diseases in women, a few points in relation to the treatment of, 448; disease in women and children, 246; infection, present methods for limiting, 788; problem, 1034.
Verbrycke, J. Russell, Jr.: gastric hemorrhage, 842.
Verminosis, the "sign of the tongue" in, 924.
Veronal, acute, poisoning simulating lethargic encephalitis, 985.
Version, method of performing, 747.
Vertigo, persistent, treatment of, with adrenine, 654.
Vessels, superior mesenteric, obstruction of the, from bands, with threatened gangrene of the greater part of the small intestine: recovery, 749.
Vibration, mechanical, and exercise therapy, 835.
Vibrations causing pulmonary physical signs, studies in, 502.
Vincent's angina, and sarcoma of the pharynx, one conditoin following the other in the order named, report of a case of syphilis, 581.
Vital capacity, a study of the effect of pulmonary tuberculosis on, 870; capacity constants applied to the study of pulmonary tuberculosis, 72; statistics, some, 609.
Virilism, suprarenal, 956.
Vision, insufficient proof of loss of, 861.
Vitamines, 244; coffee and, 906; role of, in nutrition, 359; the present status of, in clinical medicine, 408.
Vividiffusion with intestinal membranes, 649.
Volvulus of an ectopic testicle, 738.
Vomiting, cyclic, bodily mechanics; its relation to, and other obscure intestinal conditions, 328; from a surgical viewpoint, 155; habitual, in young infants, 1050; nausea and, in pregnancy, 252.

W

Waldorp, Carlos P., Castex, Mariano R., and: Rummo-Ferranini genito-dystrophic geroderma (senilism), lean type, due to tardy hereditary syphilis, 1009.
War asylums, 613; French children and the 229; loss in population, 403.
Ward, E. H. P.: notes on adrenal action, 845; notes on motility, 296.
Ware, Martin W.: an evaluation of minor surgery, 138.
Warships, obsolete, as laboratories for the study of foot and mouth disease, 985.
Wassermann reactions, the value of postmortem, 447; the value of, the, in obstetrics, based upon the study of 4,547 consecutive observations, 76, 829.
Water, boiling, hemiangioma and lymphangioma, their response to the injection of, 519; content of the body, influence of diet on the, 366; supply, city does not impliedly warwant purity of, 818; the use of, in diseases of childhood, 827.
Weakfoot in children, prevention and treatment of, 238.
Weber's syndrome, facial paralysis and, 652.
Wehle, Frank: cash premium on health, 557.
Weil's disease, 695.
Westlake, Albert: infected anices of teeth and pyorrhea alveolaris, 52.
Whooping cough, 671; an experimental and clinical therapeutic study of, 409; see also, *Pertussis;* treatment of, with ether injections, 359; use of fresh vaccines in, 369, 762; vaccines for, 950.
Wightman, Orrin S.: congenital and acquired heart conditions which give rise to symptoms; their significance and treatment, 173.
Wilcox, Reynold Webb: the therapeutics of benzosulphinide, 595.
Wildholz reaction, the, 158.

RADIUM

Radium salts of the highest purity for use in surgery and gynecology. Deliveries on the basis of U. S. Bureau of Standards measurement.

We guarantee that the radiations of our Radium salts are due solely to Radium element and its own decomposition products.

Our Medical Staff will give instruction in the physics and therapeutics of Radium.

"The National Radium Bank" instituted by this corporation.

We manufacture improved applicators, screens and other special equipment made with alloys of our own development, also apparatus for the purification and concentration of Radium emanation.

HYPEROL

(A Utero-Ovarian Tonic)

of exceptional value in the treatment of all functional diseases of women. Relieves uterine spasm, regulates the utero-ovarian circulation, stimulates physiologic processes and restores the general health. Remarkably effective in amenorrhea, dysmenorrhea, sub-involution and kindred affections. Absolutely free from all opiates or narcotic drugs.

Gray's Glycerine Tonic Comp.

an unexcelled means of improving digestion, increasing assimilation and promoting nutrition—in brief, of raising functional activity of tissue cells and thus restoring the health and vital resistance of the whole body. A reconstructive tonic of known dependability, the results from which are permanent—not transitory.

THE PURDUE FREDERICK CO.

135 CHRISTOPHER STREET NEW YORK.

LACK OF VITALITY

May be due to many causes:
The RESULT is identical, i. e.,
1. **Deficiency of Red Blood Cells.**
2. **Reduction of Hemoglobin.**

ANY DEVITALIZED CONDITION

calls for

REVITALIZATION

In such emergency depend upon

GUDE'S PEPTO-MANGAN

(LIQUID) **(TABLET FORM)**

to relieve the anemic element in Chlorosis, Amenorrhea, Bright's Disease, Chorea, Tuberculosis, Rickets, Rheumatism, Malnutrition, Convalescence.

Prescribe in original packages only—never sold in bulk.
Samples and Literature upon request

M. J. BREITENBACH CO., New York, U. S. A.

Our Bacteriological Wall Chart or our Differential Diagnosis Chart will be sent to any Physician upon request.

The Management of an Infant's Diet

In extreme emaciation, which is a characteristic symptom of conditions commonly known as

Malnutrition, Marasmus or Atrophy

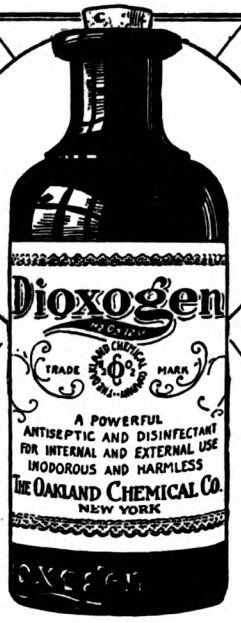
it is difficult to give fat in sufficient amounts to satisfy the nutritive needs; therefore, it is necessary to meet this emergency by substituting some other energy-giving food element. Carbohydrates in the form of maltose and dextrins in the proportion that is found in

MELLIN'S FOOD

are especially adapted to the requirements, for such carbohydrates are readily assimilated and at once furnish heat and energy so greatly needed by these poorly nourished infants.

The method of preparing the diet and suggestions for meeting individual conditions sent to physicians upon request.

MELLIN'S FOOD COMPANY, **BOSTON, MASS.**



Safe Antisepsis

is the first consideration in the treatment of infected wounds. It is not difficult to kill most of the ordinary germs. The real difficulty is to kill the germs in an infected wound without at the same time injuring or destroying the bodily tissues. With Dioxogen, however, it is easy to accomplish this, for

Dioxogen

is a selective germicide. It seems to discriminate between the bad and the good — the agencies of abnormality and disease, and the forces of nature and health. Through its liberation of a large volume of pure oxygen, Dioxogen oxidizes—burns up — harmful and pathogenic bacteria and stimulates the physiologic activity of the tissues.

How different is the action of bichloride carbolic and similar bactericides. With these the higher their germicidal potency, the greater the harm they do to the tissues. Dioxogen however, exerts even greater antiseptic power, but instead of harming the tissues, gives impetus to the processes of healing and repair.

Dioxogen is like sunlight and pure air. It is a foe to germs and septic material, but a friend to the tissues of the body.

THE OAKLAND CHEMICAL CO.,

59 Fourth Avenue **New York City**

MERCK

Genuine ICHTHYOL

is obtainable only in Bottles or Tubes under the Merck Seal and Label

CACTINA PILLETS

A dependable cardiac tonic in all functional disorders of the heart. Non-cumulative in effect, one to three Pillets as indicated will support and strengthen the cardiac muscle and promptly regulate the heart's action.

DOSE: 1 to 3 Pillets three or four times daily.

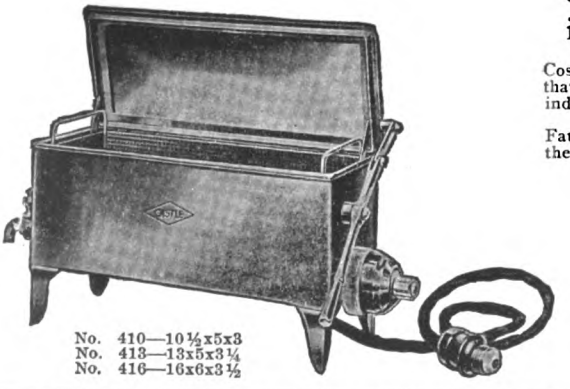
SULTAN DRUG CO. **St. Louis, Mo.**

A Sterilizer With Four New Features

Push down on the cool lever—

this opens the cover and lifts the instrument tray out of the boiling water. There are no more finger burns from steam and hot water.

The Castle automatic switch (patented) shuts off the current just before all the water is evaporated, so that you cannot overheat the Sterilizer or burn up your instruments.



No. 410—10½x5x3
No. 413—13x5x3¼
No. 416—16x6x3½

Cost of operation is reduced to a minimum by a three heat control. The switch that controls the heat is right on the end of the sterilizer and has a dial that indicates which heat is turned on.

Faucet is provided to draw off the water and make it unnecessary to disconnect the sterilizer every time it is emptied.

Castle Rochester Sterilizers are sold by the leading Surgical Instrument dealers. Information can be secured from your dealer or direct from us.

Wilmot Castle Co.

801 St. Paul St., Rochester, N. Y., U. S. A.

Makers of the largest line of Sterilizers for physicians, laboratories, hospitals and dentists.

PSYCHOPATHOLOGY

By EDWARD J. KEMPF, M.D.

Clinical Psychiatrist to St. Elizabeth's Hospital (formerly Government Hospital for the Insane), Washington, D. C.; author of "The Autonomic Functions and the Personality."

762 pages + xxiii, 6¾ x 9¾, with 97 illustrations. Printed on beautiful India tint paper, and bound in silk cloth binding, with gold stamping. Price, $9.50

A complete book on psychopathology, written by an American and elaborating the new epoch in the study and treatment of the adjudicated insane.

¶ This work on psychopathology is the first of its kind in the English language and differs decidedly from most current works on psychiatry and abnormal psychology. It does not proceed from the sterile assumption that the *brain is the organ of the mind* and the conclusion that, because in some cases undeveloped or diseased nervous tissue causes abnormal behavior, therefore in all neuroses or cases of abnormal behavior a diseased or inherently deficient nervous system or some obscure constitutional inferiority exists.

¶ In the first chapter Kempf shows how the *entire body is the organ of the mind;* showing how its visceral segments produce normal and abnormal emotional cravings and mental states.

¶ The second, third, and fourth chapters demonstrate how environmental influences distort the emotions, and the fifth chapter shows how all abnormal people are classifiable according to their dominant cravings and the manner in which they try to control them.

¶ Chapters six to thirteen discuss, with numerous case illustrations, how people develop into different abnormal types, how these types may be changed, what causes them to change and how many again readjust to normal, and why others of the same type can never become normal again.

¶ Chapter fourteen recapitulates the entire work for the student, writer, and lecturer.

¶ Chapter fifteen discusses psychotherapeutic principles and what society must do for the individual to enable him to achieve a full normal growth and healthy personality.

¶ An ample series of illustrations is used to explain the significance of common symbols to be found in dreams, delusions, hallucinations, fancies, art and ritual and why they are valuable for the emotions.

¶ The book is fully and carefully indexed in order to bring together the more important similar features to be found throughout the cases.

¶ For those who have not the time or opportunity to make exhaustive, intimate, analytical studies of normal or abnormal prople, but who need such case studies for their work as advisors, teachers, lecturers, or writers, Kempf's Psychopathology will fill an important need. It is presented to psychopathologists, physicians, sociologists, psychologists, teachers, judges, lawyers, custodians and directors of educational, military and custodial institutions to assist them to a clearer understanding of the abnormal or potentially abnormal individual.

¶ The cases are presented fully and without prudish reservation. They will be of assistance to educators and advisors on sex education in their work of keeping normal people normal.

☞This book must be seen to be appreciated. Don't bother about writing, just tear off the attached coupon, sign, and mail—but do it NOW before you lay aside this journal.

Syrup Hydriodic Acid (hydrogen iodide) ←——— **GARDNER'S** ———→ **Syrup Ammonium Hypophosphite**

are two preparations which will be found of value in the treatment of bronchitis, influenza, pneumonia, laryngitis, pharyngitis and minor coughs.

Syrup of Hydriodic Acid (GARDNER) is an excellent form of iodine for internal use and is an efficient substitute for KI and the other iodides. Iodine, it is well known, is an antiseptic, sorbefacient, glandular stimulant, alterative and eliminant; hence, destroys septic conditions, favors secretion, relieves the congestion of the affected mucous membrane and promotes the elimination of such inflammatory exudates as can be removed by absorption only. GARDNER'S Syrup of Hydriodic Acid is perfectly palatable and produces all the therapeutic effects of iodine without causing the untoward effects attending the use of the alkaline iodides, except perhaps in rare instances, and is therefore better adapted for the prolonged treatment which may be necessary in intractable cases.

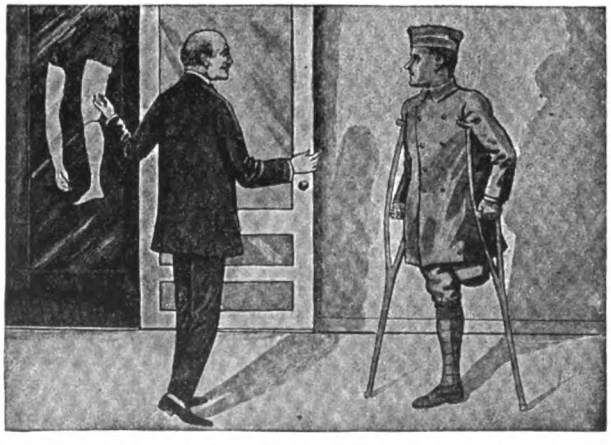
Syrup of Ammonium Hypophosphite (GARDNER), which is an active stimulating expectorant, is largely prescribed in place of ammonium chloride and carbonate and is taken much more readily than these salts because of its very pleasant taste. It liquefies and aids in the expulsion of the morbid material, the product of inflammatory processes, which obstructs the air passages and exerts a marked soothing influence upon the irritated mucous surfaces.

Sample of either or both preparations sent to physicians upon receipt of their professional card.

Firm of R. W. GARDNER

P. O. Box 925, City Hall Station **New York, N. Y.**

4 U. S. WARS
AND
MARKS HAS RE-MEMBERED THEM



Mr. Smith—Can you remember me?
Mr. Marks—Yes; step in this room.

The Marks Establishment is the oldest in the world devoted exclusively to the manufacture of artificial limbs. It has produced more artificial limbs than any other concern. It has made limbs for soldiers of four U. S. wars, as follows: Mexican, 1847; Civil, 1861-1866; Spanish, 1898, and the World War, 1917-1918.

The establishment stands to-day at the head of the profession in improvements and excellence of products. Send for Manual of Artificial Limbs. It contains 384 pages, 674 illustrations. Instructions are given how to take measurements and obtain artificial limbs without leaving home.

Anusol
HEMORRHOIDAL
Suppositories

We do not believe in **universal** remedies.

Unless it means their being **used all over the world.**

Anusol Suppositories are a case in point.

That's why the "globe" trade-mark design is so appropriate.

SPIROCIDE

(MERCUPRESSEN)

A New and Successful Treatment of Syphilis

By Fumigation and Inhalation

Spirocide is a carefully balanced combination of mercury, copper and vegetable matter, compressed into a mass weighing approximately 10 grams. This mass when ignited, burns slowly and requires 15 to 30 minutes for complete combustion.

Spirocide is the safest and most convenient form in which mercury can be administered.

Spirocide does not cause pain, and its use is attended by the least possible discomfort to the patient.

Spirocide can be administered in the office and the home; does not interfere with the patient's work or usual activities.

Spirocide is indicated in all stages of syphilis, primary, secondary and tertiary, and in all its complications or sequelæ.

Interesting case reports, together with the names of medical men who are using Spirocide, will be sent to physicians on request.

THE SPIROCIDE CORPORATION

153 West 23rd Street **New York City**

20th Century Physician

has at his elbow the knowledge, experience and discoveries of the ages to assist him in the alleviation of the ills of mankind. Nevertheless, he knows that modern medicine has produced remedial agents that in every respect far surpass anything discovered hitherto.

Especially in the treatment of chronic intestinal stasis he has learned through experience of an unvaried success in thousands of cases that "If Nature Won't, Pluto Will."

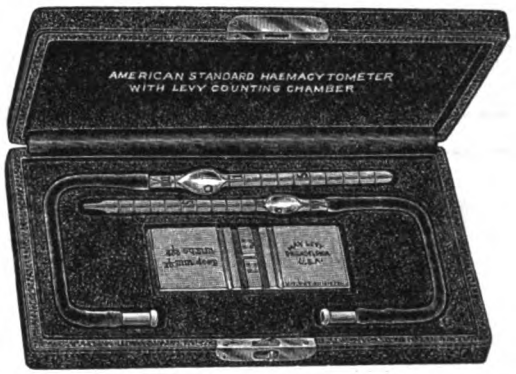
FRENCH LICK SPRINGS HOTEL CO.
FRENCH LICK, INDIANA

AMERICAN STANDARD

Haemacytometers

WITH LEVY COUNTING CHAMBER

The Levy Counting Chamber was announced in November, 1916; patented January 31, 1917 (U. S. Patent No. 1,214,331); and was awarded the Edward Longstreth Medal of Merit by the Franklin Institute, Philadelphia, December, 1917.



No. 29983 American Standard Haemacytometer with Levy Counting Chamber with Double Neubauer Ruling

THE LEVY COUNTING CHAMBER was the first dependable Haemacytometer Counting Chamber made in the U. S., and continues to be superior in several important characteristics to any chamber yet made, either in Europe or America.

It provides an increased visibility of ruling when the chamber is filled, unequalled by any ruling of European make, and a new method of construction of the parallel form of cell (first suggested by Burker), which entirely avoids the cemented cell of the Thoma or Burker construction with the attendant danger of separation from the slide.

The parallel or open form of chamber permits the filling of the ruled area on the cover glass by capillary attraction after the cover glass is in position on the slide, and provides a more uniform distribution of the corpuscles than is possible with the Thoma or circular form of counting chamber which is entirely closed by the cover glass.

The dimensions of the ruling and the depth of the cell are guaranteed to be within the tolerances established by the Bureau of Standards and, when so ordered, Counting Chambers are furnished with Bureau of Standards certificate at an additional price.

29991. American Standard Haemacytometer, complete with Levy Counting Chamber with Neubauer ruling, with two pipettes, in leather case..... **$15.00**
29992. ditto, with Bureau of Standards certificate, **22.00**
29983. American Standard Haemacytometer, same as No. 29991 but with Levy Counting Chamber with double Neubauer ruling.. **18.00**
29984. ditto, with Bureau of Standards certificate, **26.00**

Prices subject to change without notice.

To be had of dealers generally, or mailed direct by prepaid, insured parcel post to any part of the world when remittance accompanies order.

LIBERAL DOSAGE—MINIMUM EXPENSE

In specializing on Bacillus Bulgaricus Cultures under the scientific guidance of Professor Metchnikoff since 1906 and by constant co-operation and collaboration with eminent medical practitioners, we have arrived at the conviction that **adequate dosage** is one of the most important factors in the effective application of the Bacillus Bulgaricus to therapeutic purposes. Seven c.c. tubes have brought satisfactory results in cases where long-continued use of tablets showed no improvement whatsoever, and the administration of one ounce or two ounce doses, once or twice daily, gave surprisingly rapid results where the 7 c.c. doses had proved of little benefit, even when administered three to six times daily.

Acting on this scientific conclusion, we have worked out the problem of LIBERAL DOSAGE—MINIMUM EXPENSE. We have always maintained, and still steadfastly maintain, that it is unscientific and even dangerous to dispense culture media in bulk. Our reason for this has been clearly set forth for years on page 6 of our Physician's List. We have, therefore, introduced the "small drink" dose in individual, one-dose bottles.

THE BIG THREE

(Actual Size)

"PINEAPPLE CULTURE, METCHNIKOFF." A two-ounce dose of Culture A in each bottle. Suitable for all cases of autointoxication, except Diabetes, or where fruit juices are counter-indicated. Price per case of one dozen bottles, delivered to patient's address, anywhere east of Mississippi River. $2.00.

"WHEY CULTURE, BACILLUS BULGARICUS, METCHNIKOFF." A one and one-half ounce dose in each bottle. Suitable for colon injection and all cases where a fruit juice medium is not desired. Price per case of one dozen bottles, delivered to patient's address, anywhere east of Mississippi River. $2.25.

"BULGARICUS BOUILLON, METCHNIKOFF." For Diabetics. A one and one-half ounce dose of Culture D in each bottle. The most valuable therapeutic agent for the treatment of Diabetes known to medical science. Price per case of one dozen bottles, delivered to patient's address, anywhere east of Mississippi River. $2.25.

All the above products can be obtained at the leading druggists or will be delivered at patients' address without extra charge.

Extension heel restores the correct balance of the body when walking and standing. The long counter, shown by dotted line, helps in reshaping the metatarsal arch. Women's model is pictured here.

Renew Your Walking Power

Long experience with feet that have strayed from good health gives us the knowledge to make the Coward Arch Supporting Shoe.

It is so designed as to reshape the region of the instep accurately and normally. The extension heel adjusts the weight of the body. The long counter and elastic span below gradually remold the arch structure and bring it back to natural usefulness. The women's model is pictured here.

Quotations from Doctors: No. 8

"Recently I was called to see a pneumonia case and found the man in a very bad condition—disease allowed to run several days without medical assistance. Examination revealed complete consolidation of the lower lobe of right lung; severe dyspnea, temperature 104 F., high pulse—cyanosis.

"I left some medicine from my pocket case—ordered a large can of

Antiphlogistine
TRADE MARK

no wrapper on can—only my own directions. It was correctly applied—patient's son reported next day father much better. Following morning found patient greatly improved—he was restful—free from pain; cyanosis gone, temperature lowered. Patient said: "I don't know what the application was, but I am certain it saved my life."

JUMP AT CONCLUSIONS—FALSE DIAGNOSIS

The therapeutic value of pure petroleum oil has been established, in spite of the reaction resulting from over exploitation of and exaggerated claims for it.
Proper use of a perfected product assures satisfactory results.

TERRALINE

(Petroleum Purificatum)

a pioneer preparation of medicinally pure petroleum oil, bland, palatable and standardized, has for years demonstrated its value both as an intestinal lubricant and especially in the treatment of bronchial irritation, for the relief of cough to promote expectoration and assist in the healing of inflamed areas.

Terraline is supplied either plain or with Creosote or Heroin. Terraline has been tested and proven by thousands of physicians, to whom it has appealed on account of its quality, its ethical introduction and its convincing response to the acid test of actual performance. Terraline forces conviction because it brings results.

Samples and literature to physicians only on request.

HEYDEN

Colloidal Silver Salts and Mercury Preparations in Genito-Urinary Practice

PROGANOL-HEYDEN—A non-irritating silver proteinate preparation of high efficiency. Especially useful in acute and chronic gonorrhea.

VARGOL-HEYDEN (Formerly Vitargol)—Contains about 25 per cent of silver in organic combination, is readily soluble, non-irritating and has a high penetrating power. Especially useful in urethritis and cystitis.

CALOMELOL OINTMENT—An anti-syphilitic preparation containing the equivalent of about 30 per cent of metallic mercury in soluble form and is very readily absorbed through the skin without causing any of the unpleasant effects that follow the use of mercurial ointment by inunction.

INJECTION-HEYDEN—Is a one per cent solution of oxycyanide of mercury put up in ampoules for injection in those cases of syphilis where it is deemed advisable to introduce mercury within the tissues. The injection of this solution has been rendered painless by the addition of Novocain.

We will gladly send you samples and literature.

HORMOTONE IN GYNECOLOGY

Owing to the reciprocal relationship that exists between the glands of internal secretion, a functional disorder of them is, in its last analysis, always a pluriglandular disturbance—never a monoglandular malady. As Blair Bell puts it: "A woman is what she is on account of the sum total of her internal secretions."

HORMOTONE

is a pluriglandular preparation of proven value in

Menstrual and Menopausal Disorders

The following reports from physicians are of interest:

"I used Hormotone with satisfactory results in a case of amenorrhea. The nervous symptoms, which were alarming, were promptly corrected and the menstrual flow restored."

"I have used Hormotone in the case of a young lady suffering from dysmenorrhea, fainting and prostration at period, which was the cause of her losing her position as a stenographer. After being on Hormotone for five months she is entirely free from pain and there is a notable gain in her general condition of nutrition."

"I have noted exceptionally good results with Hormotone in that type of neurasthenia associated with the menopause."

In menopausal conditions associated with hypertension, use

HORMOTONE WITHOUT POST-PITUITARY

Dose of either preparation: One or two tablets three times daily before meals.

Why Betul-ol?

Cutaneous absorption of drugs gives results somewhat similar to their injection hypodermically, since it is an osmotic passage through the tissues into the blood.

Wintergreen oil (or methyl salicylate) is one of the many drugs which is easily absorbed by the skin, and the most reliable of this class of salicylic liniments is BETUL-OL, a menthol-methyl-salicylate.

Grains
Puffed to Bubbles
Food Cells Exploded

We seal the whole wheat in guns and roll it for an hour in 550 degrees of heat. The trifle of moisture in each food cell is thus changed to steam.

When the guns are shot, over 100 million steam explosions occur in every kernel.

The food cells are blasted for easy digestion. The grains are puffed to bubbles, thin, flimsy and crisp, eight times normal size.

Puffed Rice is whole rice puffed in like way. Corn Puffs are corn hearts puffed.

Puffed Grains, we believe, are generally considered the ideal form of grain food. No other process so fits cereals for. digestion.

Puffed Rice
Corn Puffs

How I Lost a Patient

About 3 weeks ago a man came to my office with a badly infected hand. He was suffering great pain. A bright red streak extended to the axilla, where I found a large and very tender lymphatic. I opened the hand and cleaned out a number of abrasions, using a bichloride of mercury solution. I dressed the hand several times later with little or no improvement. Then he passed into other hands and I did not blame him in the least.

About a week later one of his companions came in with an exactly similar condition. The second man I treated solely with Dionol, making three applications only, with complete relief. It is needless to say I shall certainly use Dionol again.

Rent This TYCOS Nine Months Then It's Yours

$2.50 Monthly Brings It

The celebrated Blood Pressure Apparatus, Dr. Rogers' Sphygmomanometer is very accurately made and registers both systolic and diastolic pressures. The cash price of the Tycos everywhere is $25.00. We will send it to you on receipt of only $2.50 and, if after ten days' trial, you wish to keep it, simply pay the balance—$22.50—the same as rent—in nine monthly payments of $2.50 each. At the end of that time it is your absolute property. You pay only the cash price (no interest—no extras) and have nine full months in which to make it pay for itself.

Leather Case and Booklet Free

With every Tycos is included **Free** a genuine morocco leather case. You can put your Tycos into this case and carry the entire instrument in your pocket. Besides the case, we give you **Free**, a 44-page booklet which explains accurately, thoroughly and plainly just how and why the Sphygmomanometer is essential to the intelligent practice of medicine.

Ten Days' Trial—Money Back

Send today. Just say that you saw our offer in the Journal of American Medical Association. Enclose $2.50 for first month's rent and we will immediately send you the instrument, and you will only have to pay $2.50 every succeeding month until the cash price, $25.00, is paid in full. Send that $2.50 today—first come—first served. The orders are going to come thick and fast, so you will have to hurry. We give ten days' trial and return your money if you are not satisfied. CASH PRICE. The price for all cash with order is just the same, $25.00. We make no distinction.

MANUAL OF TOXICOLOGY

BY

R. A. WITTHAUS, A.M., M.D.

Professor of Chemistry, Toxicology and Medical Jurisprudence in Cornell University; Emeritus Professor of Medical Chemistry and Toxicology in the University of Vermont.

Being the Fourth Volume of Witthaus's and Becker's "Medical Jurisprudence, Forensic Medicine and Toxicology."

SECOND EDITION

The author is probably better qualified than anyone else to produce a book on this subject, having devoted the major part of his life to the study of Chemistry and Poisons, and to the art of the detection of the latter. The subject is handled in the following order: First, there is a Table of Cases, giving references by page to the "causes célèbres" quoted in the book. Then, next, an introductory article, Historical and Biographical. Following this is a section devoted to General Toxicology. The major part of the book is devoted to Special Toxicology. In this section the individual toxic agents, classified into: Mineral Poisons; Metallic Poisons; Vegetable Poisons; Animal Poisons, and Synthetic Poisons are each considered at length. The foot-notes are very numerous. The references contained in them have all been personally verified by the author, and give the original source of every quotation in the text. A very large Index concludes the volume.

Large octavo volume, 1271 pages, illustrated. Extra muslin, $7.00 net; brown sheep, $8.00 net.

LOESER'S INTRAVENOUS SOLUTIONS

Iron and Arsenic

THE red blood cells play a vital rôle in resistance and repair. They do more than merely carry oxygen. Arsenic and Iron, when given intravenously, produce a rapid, certain, efficient increase in hemoglobin and red cells. The period of disease as well as that of recovery is tremendously shortened by putting iron and arsenic directly into the blood stream by injecting Loeser's Intravenous Solution of Iron and Arsenic. The intravenous method is safe, simple, satisfactory. No dangerous or depressing after effects. Prompt response. Patients appreciate the rapid return to health and physicians who employ the intravenous method will use no other.

Loeser's Solution of Iron and Arsenic is indicated in—

Anemia	**Psoriasis**	**Malaria**	**Pericarditis**
Syphilis	**Tuberculosis**	**Pellagra**	**Neurasthenia**

Clinical Reports, Reprints, complete list of Intravenous Solutions, Directions for use, Prices, etc., will be sent to any physician on request.

FOOD
AND THE PRINCIPLES OF DIETETICS

By ROBERT HUTCHISON, M. D., Edin., F. R. C. P.
Physician to the London Hospital and to the Hospital for Sick Children, Great Ormond Street

Fourth Edition, 1917

THE work entirely covers the subject in a most detailed and comprehensive manner, describing the nature, nutritive constituents, and relative values of food; the amount of food required in health; the influence of various conditions upon the amount of food required; animal food, jellies, fish, soups, beef extracts, beef juices, beef tea and beef powders; milk, foods derived from milk, cheese, eggs and egg substitutes; vegetable foods, cereals, wheat-bread, roots and tubers; fruits, nuts, sugar and spices; water and mineral waters; tea, coffee, cocoa, alcoholic beverages and wines. The cookery of foods, the digestion of food in health, feeding in infancy and childhood, and feeding in disease.

In this edition the whole book has been thoroughly revised, and many minor alterations and additions affected. A section has been added on the subject of Vitamines. The term "Protein" has been substituted for "Proteid" throughout the book.

The book is written in a style calculated to make it very interesting aside from its usefulness as a work of reference.

What Was Said of the Former Edition

PROFESSOR W. O. ATWATER
Wesleyan University
"Hutchison's Food and Dietetics seems to me decidedly the best work of the kind with which I am familiar. No other book I know gives so good an account of the results of the latest experimental inquiry regarding food and nutrition."

EDWARD ATKINSON, L.L.D., Ph.D.
"The latest, most complete, and most useful work."

ISABEL GORDON CURTIS
"This book is splendidly comprehensive and must prove itself a most valuable addition to the library of anyone interested in the study of foods. To-day this class is a very large one, including specialists, doctors and nurses."

FANNIE MIRRET FARMER
Principal Boston Cooking School.
"It holds a high place among books of its kind."

Octavo, 627 pages, illustrated by plates and charts. Muslin, $4.50 ***net.***

Course of disease is shortened to 11 to 14 days.

A solution prepared in the laboratories of A. & G. Pecoul, Paris, France.

Obtained by double electrolysis; consisting of colloidal bismuth. Is colorless, odorless, tasteless, with the palatability of spring water and lends itself to easy administration in children.

Does not contain opium or its derivatives, nor does it contain chloral bromides, or other sedative drugs. Its prophylactic value is definite.

Used successfully in the Treatment of Pertussis in Europe and South America.

We take great pleasure in recommending Soderseine to the profession.

Dosage should be ample.

For infants, Sig: Three tablespoonfuls q 3h.

For older children, Sig: Four tablespoonfuls, t. i. d. a. c.

Prophylactic dose, Sig: Two tablespoonfuls, t. i. d. a. c.

SANITUBES

In all discussions about the venereal problem try to find a better method of medical prophylaxis than SANITUBES. The more it is investigated the more favorable is the opinion. SANITUBES have been tested and approved by the Pennsylvania State Department of Health.

THE SANITUBE COMPANY, NEWPORT, R.I.

MANUAL OF SURGERY

(ROSE AND CARLESS)

For Students and Practitioners

TENTH EDITION

By ALBERT CARLESS, C. B. E., M. B., M. S., Lond., F. R. C. S.

Colonel (Temp.), A.M.S.; Consulting Surgeon, Eastern Command; Emeritus Professor of Surgery to King's College, London, and Consulting Surgeon to King's College Hospital; Formerly Examiner in Surgery to the Universities of London, Glasgow, Manchester, Liverpool and Leeds, and to the R.A.M.C., etc.

In the present edition the author was faced by the problem of determining the ultimate value in civilian work of the many and diverse methods which have been introduced as war-time emergencies. In three chief directions has new and valuable work been done, viz., in the treatment of infected wounds, in dealing with compound fractures, especially of the shafts of long bones, and in making good the defects of war-wounds; and in the sections devoted to these subjects considerable expansion has been necessitated. Many new illustrations have been added and X-ray pictures have been gathered into a Radiographic Supplement and printed on art paper.

Octavo, 1586 pages, sumptuously illustrated by 16 colored plates and 614 engravings. Muslin, $8.00 net.

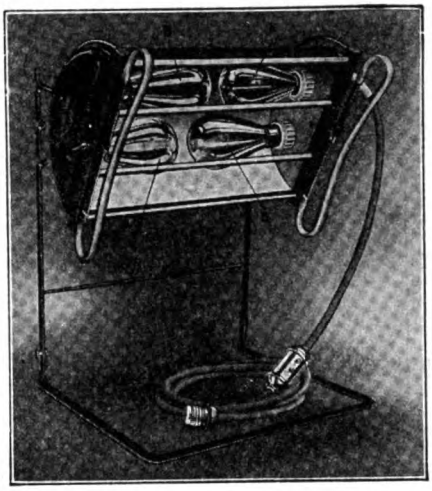
Physicians' Rental Service



Applicator on Stand

This unique Department has been developed by request of physicians who know the results of LIGHT and HEAT APPLICATIONS properly made, and who wish to write prescriptions for their use in particular cases under their personal supervision in the patient's home. These APPLICATORS are a most effective aid in a large class of cases, such as the relief of *pain, elimination* by *sweating, active local or general hyperaemia, increasing general nutrition*, etc., etc.

"We have found this applicator exceedingly valuable in the treatment of all forms of infections of the extremities, peritonitis, X-ray burns, etc. We have a considerable number of them in daily use at Augustans Hospital. Any physician who uses it once will always use it. It does the work and gets the results."

ALBERT J. OCHSNER, M.D., LL.D., F.A.C.S.
Chicago, Ill

The Rental service is given only upon the Physician's Prescription and the charge for same will be $5.00 for the first month and $4.00 for succeeding months, payable in advance.

Pond's Extract ——— Purity and Quality

It is not difficult to account for the fact that results are obtainable with Pond's Extract that are generally impossible with ordinary extracts of hamamelis. One has only to consider the purity, quality and unvarying uniformity of Pond's Extract to understand not only its therapeutic efficiency, but also its widespread recognition as the standard preparation of hamamelis. For over seventy years it has been meeting the requirements of the medical profession, dependably and well. POND'S EXTRACT CO., New York and London

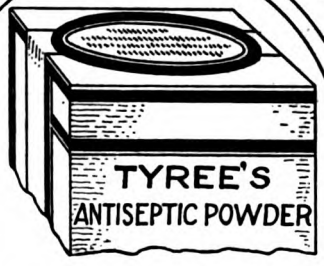
Tested *for* Quality



A Specific in the Treatment of Leucorrhoea

The therapeutic value of Tyree's Antiseptic Powder

As a prophylactic it is of paramount importance, rendering the tissues with which it comes into contact unfit media for the development of pathogenic bacteria. As a daily douche, germ invasion is almost impossible, being cleansing, deodorant, astringent and curative. We cannot quote anything more convincing than the following communication from Dr. W. M. Gray, Microscopist to the Army Medical Museum, Washington, D. C.:

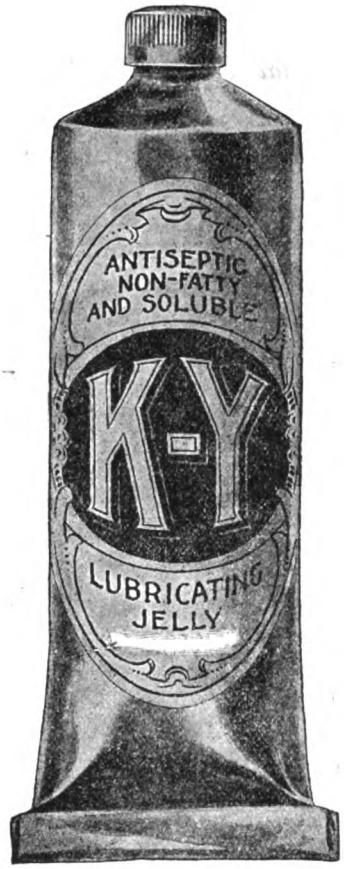
This is to certify that the exact antiseptic strength of "Tyree's Pulv. Antiseptic Comp." is one part of the powder to fifty of water (1:50). Test tubes containing peptonized beef broth were charged with the powder (Tyree's Antiseptic Powder). The solutions were then inoculated with the anthrax bacillus, and with the staphylococci of pus, and the tubes placed in the incubator for 48 hours at a temperature of 390° C. On removing the tubes from the incubator, it was found that in the solutions of one in ten to one in fifty there was no development of bacteria.

J. S. TYREE, Chemist, Inc. Washington, D. C.

K-Y LUBRICATING JELLY

THE PERFECT SURGICAL
LUBRICANT

Assures effective surgical lubrication without staining the clothing, as it contains no grease. It is soluble in water; is antiseptic and is non-corrosive to instruments



K-Y LUBRICATING JELLY

AN IDEAL
EMOLLIENT

Promotes "hand comfort" by safeguarding against the ravages of antiseptic solutions, hard water and severe weather. Allays smarting, soothes irritation

So many cases of Pruritus, Chafings and Irritations are relieved by applying **K-Y Lubricating Jelly** that the profession's attention is respectfully directed to the fact. No claim is made that K-Y Lubricating Jelly will act with equal efficacy in every case, but you will secure excellent results with such a large number of patients that we believe you will continue its use as a matter of course. *Samples on request*

HEADACHE and NEURALGIA

can usually be promptly relieved and often completely removed by the liberal use of

K-Y ANALGESIC

Rubbed in gently but thoroughly over the affected area, pain and ache soon yield to the sedative action of this safe and dependable local anodyne. Non-greasy, water-soluble and non-staining, K-Y Analgesic may be used as freely or as frequently as may be necessary to accomplish the result desired.

The previous application should always be washed off before applying the next.

Entered as Second-Class Matter, June 24, 1879, at the Postoffice at New York, N. Y., under act of March 3, 1879.

Apothesine in Minor Surgery

THE brilliant success that has attended the use of Apothesine as a local anesthetic in major surgical procedures suggests its broader application in the vast field of minor surgery.

This appeals especially to the general practitioner, who is daily called upon to perform minor operations in which the administration of ether is scarcely feasible.

Here Apothesine is the anesthetic of choice. It is a stable synthetic substance; it is fully as efficient as cocaine, while relatively less objectionable; its effect is prolonged; it is not toxic in the amounts used to produce anesthesia, nor is it destructive to tissue; its solutions can be sterilized by boiling.

Apothesine is supplied in the form of crystals, tablets and solution of 1½% strength with 1:60,000 Adrenalin. The solution, which is put up in 20-cc and 2-ounce vials, is ready for immediate use.

Our advantages make us headquarters for the organo-therapeutic products

The Importance of a Hematinic in Syphilis

Practically every case of syphilis at one stage or another, suffers from the destructive influence of the virus on the corpuscular elements of the blood serum. The plan of treatment of most physicians embraces a blood maker, and the QUICK RESPONSE OF SYPHILITIC CACHEXIA to

Extract of Red Bone Marrow

(Medullary Glyceride)

indicates that its selection for the purpose is most logical.

Prepared from fresh red bone marrow—the function of which seems to be the regeneration of blood corpuscles—this product may be depended upon as an effective blood builder and flesh maker.

Armour's

Sterile Surgical Catgut Ligatures — plain and chromic — regular (60-inch), emergency (20-inch), sizes 000 to No. 4 inclusive, are smooth, strong, and "just what a ligature should be."

LABORATORY PRODUCTS

LISTERINE

A Non-Poisonous, Unirritating Antiseptic Solution

Agreeable and satisfactory alike to the Physician, Surgeon, Nurse and Patient. Listerine has a wide field of usefulness, and its unvarying quality assures like results under like conditions.

As a wash and dressing for wounds.
As a deodorizing, antiseptic lotion.
As a gargle, spray or douche.
As a mouth-wash-dentifrice.

Operative or accidental wounds heal rapidly under a Listerine dressing as its action does not interfere with the natural reparative processes.

The freedom of Listerine from possibility of poisonous effect is a distinct advantage, and especially so when the preparation is prescribed for employment in the home.

COUGHS and BRONCHIAL AFFECTIONS

Respond promptly to

ANGIER'S EMULSION

The proven efficacy of Angier's Emulsion in cases of COUGHS and BRONCHIAL AFFECTIONS warrants it being given a trial in your practice. It is particularly useful for elderly people and children because it is pleasant to take and causes no digestive disturbance. Its use obviates the necessity of administering disturbing or depressing drugs or narcotics.

Samples on request

"If you are not familiar with the Emulsion and you have a case where you would like to try some samples, we will send them, charges prepaid, on request."
